The family must be informed of the immediate care needs of the postoperative child, especially in outpatient surgery cases in which the presence of two caretakers may be necessary for the trip home afterward. The rise of ambulatory surgery over the past decade, especially in the realm of tonsillectomy surgery where inpatient stays decreased by 54% from 1996 to 2006, is of obvious importance to pediatric otolaryngologists (70). The anesthesia team plays a special role in the ambulatory surgery setting. The use of sedative, antiemetic, and anesthetic agents can be varied to result in a more alert, less systemically ill, postoperative child.

CONCLUSION

The subspecialty of pediatric otolaryngology has grown from that of a few individual otolaryngologists in the 1960s to the degree that most major medical centers in this country now have several pediatric otolaryngologists on their full time staffs. An increasing percentage of community–based otolaryngologists also devote their careers principally or solely to pediatric otolaryngology. Pediatric otolaryngology fellowships currently exist at many academic otolaryngology institutions, and attempts are underway to formalize and uniformly accredit pediatric otolaryngology fellowship training from a didactic instruction, clinical responsibility, and research experience standpoint (71,72). These fellowships produce otolaryngologists committed to caring for the ear, nose, and throat disorders of children. The work of these individuals will continue to benefit their own pediatric patients directly, and their

accomplishments will indirectly strengthen the comprehensive management of otolaryngologic diseases in children for our specialty overall.

HIGHLIGHTS

- The subspecialty of pediatric otolaryngology focuses on a specific age group rather than a single organ system or category of disease. It is best defined as the study of the disorders of the ears, nose, and throat relative to the growth and development of the head and neck structures.
- Marked anatomic, physiologic, and behavioral changes occur along the continuum from infancy through childhood and adolescence into adulthood. The clinical presentation of any otolaryngologic disease process is greatly influenced by the age and maturation of the afflicted person.
- Children with congenital malformations of the head and neck require a thorough general pediatric assessment to ensure that their otolaryngologic anomaly is isolated and not a manifestation of a systemic syndrome. The discovery of additional syndromic anomalies could change both acute and chronic treatment plans significantly.
- Refinements in endoscopic instrumentation have influenced multiple aspects of pediatric otolaryngologic care. This is particularly true in the diagnosis and management of congenital and acquired airway lesions and the surgical treatment of paranasal sinus disease.
- Of the sensory impairments of relevance to pediatric otolaryngology, none is of greater significance than hearing loss. Otolaryngologists who care for children must be knowledgeable about the expected developmental milestones of receptive and expressive language from both a diagnostic and rehabilitative standpoint.
- Universal newborn hearing screening programs are designed to identify children with congenital or neonatal-acquired hearing loss. The goal of such screening programs is the institution of amplification, when needed, between 6 weeks and 3 months of age.
- Refinements in angiographic embolization, microvascular techniques, and craniofacial approaches have broadened the definition of resectability without deformity in many children with extensive benign or malignant head and neck neoplasms.
- Bilateral and unilateral vocal fold paralysis present different problems in diagnosis and management. An overall conservative approach to treatment is recommended in light of the increased likelihood of adequate compensation in children, especially in idiopathic and neurogenic cases.
- Sleep disordered breathing accounts for the majority of pediatric adenotonsillectomy cases. Significant postoperative improvement in quality of life is documentable in children even in the absence of polysomnography-confirmed apnea.
- Continued research is needed in such dedicated pediatric arenas as the genetics of hearing loss, the neuromaturation of the auditory and speech pathways, and the potential adverse effects of imaging radiation and general anesthesia on the developing child.
- Multidisciplinary collaboration likely improves the care of medically complex children. Creative coordination among all parties involved will be necessary to prove this to be the case in an era where health care delivery will likely undergo significant change.
- Children are not cared for in isolation. All pediatric otolaryngology encounters are influenced to some degree by the close identification and vested interest of the parent(s) and other family members with the ill child.

87 Congenital Aerodigestive Tract Anomalies

Christopher T. Wootten *Charles M. Myer III*

EMBRYOLOGY AND PATHOPHYSIOLOGY OF THE UPPER AERODIGESTIVE TRACT

The aerodigestive tract includes an array of organs and tissues with specialized roles that begins at the nares and lips proximally and ends at the stomach and bronchioles distally. Despite the disparate anatomy, these organs and tissues are united around three common functions: feeding, breathing, and voicing. Disease at any level of the aerodigestive tract often affects all three functions. Congenital malformations of the upper aerodigestive tract usually relate to errors in the embryonic phase of development. Dividing anomalies by anatomical region provides organizational structure to the differential diagnosis and aids in the formulation of a focused and cost-effective diagnostic algorithm. A comprehensive list of congenital aerodigestive tract diseases by anatomical location is given in Table 87.1. Aerodigestive embryology is reviewed below.

Nasal and Nasopharyngeal

The stomodeum is surrounded by the frontonasal prominence superiorly, the maxillary processes laterally, and the mandibular processes inferiorly. Normal nasal development occurs during weeks 4 through 12 of intrauterine life. Within this timeframe, the foramen cecum provides communication between the prenasal space and the anterior neuropore. The nasal placodes, which are two small thickenings in the frontonasal prominence, burrow to form nasal pits (Fig. 87.1). This invagination process in the fifth week creates ridges of tissue around the pits called the lateral nasal prominences laterally and the medial nasal prominences medially. The nasolacrimal ducts develop as ectodermal thickenings that become buried in the mesoderm of the nasal pits between the lateral nasal prominence and the maxillary process. This buried ectoderm eventually canalizes from superiorly to inferiorly. The lateral nasal prominences form the nasal alae. Posteriorly, the nasal pits develop into the pouches of the nose and paranasal sinuses that reside above the oral and buccal cavities. The nasobuccal membrane separates the nasal and oral–buccal spaces, and eventually this membrane ruptures and obliterates (1). Several gene products have been identified that play regulatory roles in posterior nasal development, including PTPN14 (2), TBX22 (3), and CHD7 (mutated in greater than 50% of patients with CHARGE syndrome) (4).

Oral

As early as the third week, the branchial arches are demonstrated surrounding the foregut and primitive oral cavity, or stomodeum. The stomodeum is separated from the developing nose by the nasobuccal membrane and from the developing foregut by the buccopharyngeal membrane, the latter corresponding to the region of the palatine tonsils. The mandibular arch begins to grow anteriorly around the third week, enlarging the stomodeum. The mandibular arch subdivides into a maxillary and mandibular process, and the paired maxillary and mandibular processes from each side eventually fuse in the midline along neural crest cell migrations (5). Recalling nasal development, the lateral and medial prominences finalize interaction with the developing maxillary process, creating the philtrum and medial lip (from the fused medial nasal prominences) and the lateral upper lip (from the maxillary prominences). As palatal development occurs, the deepening nasal pits become separated from the developing oral cavity and tongue. Oral–nasal patterning of the palate as well as some aspects of oral cavity and tongue development (e.g., the development of taste buds) is under sonic hedgehog (Shh) regulation (6–10). Palatal development

TABLE 87.1 TYPES OF CONGENITAL AERODIGESTIVE TRACT ANOMALIES BY ANATOMIC ZONE

Nose/Nasopharynx	Oral	Oropharyngeal	Hypopharyngeal/ Laryngeal	Tracheobronchial/ Esophageal
Pyriform aperture stenosis	Median mandibular cleft	Vallecular cyst	Branchial fistula	TEF
Facial clefts	Micrognathia	Lingual thyroid	Choristoma	EA
Nasolacrimal duct cysts	Cleft lip	Lingual thyroglossal duct cyst	Pharyngeal bands	Complete tracheal rings
Hemangioma	Cleft palate	Teratoma	Hemangioma	Tracheomalacia
Teratoma	Midpalatal cyst of infancy	Maxillary duplication	Vascular malformation	Deficient tracheal rings
Dermoid	Nasolabial cyst	Persistent buccopharyngeal membrane	Cricopharyngeal bar	Tracheomegaly
Glioma	Nasopalatine duct cyst	Hamartoma	Laryngomalacia	Tracheal agenesis
Encephalocele	Labial frenulum	Glossoptosis	Vocal cord paralysis	Bronchogenic cyst
Choanal atresia	Oral synechia	Macroglossia	Subglottic stenosis	Tracheal bronchus
Thornwaldt cyst	Lip pits	Leiomyoma	Posterior glottic stenosis	Laryngotracheal stenosis
Epulis	Astomia	Desmoid fibromatosis	Laryngotracheal cleft	Epidermolysis bullosa
Salivary gland anlage tumor	Microstomia	Branchial fistula	Bifid epiglottis	Tracheal pouch/tracheocele
Hamartoma	Congenital macrostomia	Pharyngeal bands	Epiglottic cyst	Hemangioma
Proboscis	Ankyloglossia	Ectopic parotid tissue	Laryngeal saccular cyst	Vascular malformation
Ossifying fibroma	Median rhomboid glossitis	Ectopic carotid	Laryngocele	Chondroma
Pyogenic granuloma	Fissured tongue	Vascular malformation	Laryngopyocele	Chondrosarcoma
Infantile myofibromatosis	Macroglossia	Hemangioma	Epiglottic agenesis	Esophageal duplication cyst
Hemangiopericytomas	Lingual thyroid	Pharyngeal auricle	Epiglottic hypoplasia	Esophageal stricture
Lipoma	Lingual thyroglossal duct cyst	Encephalocele	Laryngeal web	Dysphagia lusoria
Chondroma	Microglossia		Laryngeal atresia	Broncho–biliary fistula
Chordoma	Aglossia		Submucous laryngeal cleft	Tracheal web
Schwannoma	Epidermoid cyst		Laryngoptosis	
Pleomorphic adenoma	Dermoid cyst		Subglottic hemangioma	
Rhabdomyosarcoma	Lymphoepithelial cyst		Hamartoma	
Soft tissue sarcomas	Mucocele		Sulcus vocalis	
Birth trauma	Ranula		Laryngeal cyst	
	Bohn nodule		Pachyonychia congenita	
	Natal teeth		Ectopic thymic cyst	
	Epulis			
	Choristoma			
	Lymphatic malformation			
	Hemangioma			
	Proteus syndrome			

is complex, and the numerous steps involved are detailed elsewhere in this text.

Oropharyngeal

Posteriorly, the tongue develops from multiple branchial arch contributions. Around the fourth week, four regions fuse to form the tongue: paired lateral lingual swellings (first arch derivatives), a midline lingual swelling (first arch derivative), and a hypobranchial eminence (second, third, and fourth arch derivatives). The first arch-derived tongue lies anterior to the buccopharyngeal membrane and constitutes the oral tongue that represents the anterior two-thirds of the tongue's length. In contrast, the portion of the tongue derived from the hypobranchial eminence becomes the oropharyngeal, or posterior one-third of the tongue. As the four zones of the tongue fuse, the lateral lingual swellings override the midline lingual swelling, which comes to be known as the tuberculum impar. Immediately posterior to the tuberculum impar is a V-shaped sulcus (the sulcus terminalis) that separates the tuberculum impar from the hypobranchial eminence, now known as the copula. In the midline of the sulcus terminalis is a zone known as the foramen cecum, which is the origin of the mesodermally derived thyroid gland (Fig. 87.2) (5).

Figure 87.1 Lateral and frontal drawing of a human embryo around 5 weeks. *1*, lateral nasal prominence; *2*, medial nasal prominence; *3*, maxillary process; *4*, mandibular process; *5*, stomodeum. Adapted from Nelson, 1953.

Hypopharyngeal and Laryngeal

Posterior to the hypobranchial eminence (inferior in postnatal life), the larynx appears as a thickening along the ventral aspect of the foregut around 28 days. The caudal portion of the hypobranchial eminence (also known as the furcula of His) gives rise to an epiglottic anlage by 33 days.

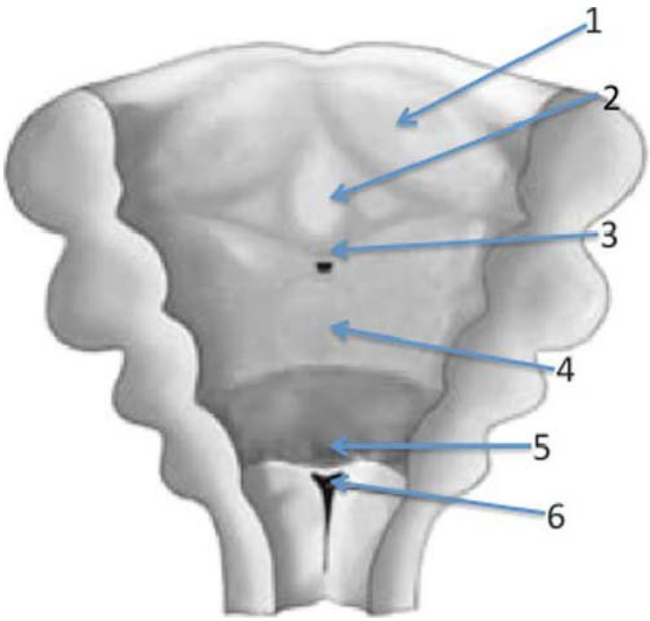

Figure 87.2 Posterior coronal illustration depicting the developmental anatomy of the tongue around the fifth week of development. *1*, lateral lingual swelling; *2*, tuberculum impar; *3*, sulcus terminalis; *4*, hypobranchial eminence (copula); *5*, epiglottic anlage; *6*, glottic inlet.

Paired fourth branchial arches contribute to the epiglottis and the aryepiglottic folds, but the hypobranchial eminence may also have unpaired midline derivatives. By 48 days, the vallecular space is well-defined enough to distinguish the epiglottis from the tongue (11). Inferiorly, the respiratory primordium develops an outpouching from the floor of the pharynx that begins to proliferate posteriorly. This laryngotracheal complex becomes continuous with the ventral lung buds. Obliteration of the ventral lumen of the primitive laryngopharynx gives rise to the epithelial lamina of the larynx. The pharyngoglottic duct is located dorsal to the epithelial lamina, and the laryngeal cecum (primitive vestibule) is located anterior to it. The epithelial lamina recanalizes to open into the laryngeal cecum and allows the pharyngoglottic duct to unite with the cecum, forming the vestibule (from the cecum) and the interarytenoid notch/posterior glottis (from the pharyngoglottic duct) (12). Beneath these epithelial movements, mesenchymal contributions from the paired fourth and sixth branchial arches comprise the cartilaginous framework of the larynx and its supporting nerves and vessels.

Tracheobronchial and Esophageal

Again, around 28 days, the anterior foregut begins to partition into a dorsal esophagus and a ventral trachea that connects to simultaneously developing ventral lung buds off the primitive foregut. The molecular mechanisms driving this early partition include the localized expression of *Nkx2-1* (*Tif1*) in the ventral wall of the anterior foregut, while Sox2 expression predominates dorsally. Patterning of *Nkx2-1*/Sox2 expression is in turn signaled by the expression of Bmps, noggin, Fgfs, Shh, and Wnts in the surrounding mesenchyme. Abnormalities in these mesenchymal signals can result in failure of foregut separation and abnormal differentiation of the epithelium and mesenchyme, including tracheal agenesis (13). Tracheoesophageal separation is a dynamic process that involves inward movement of lateral mesodermal ridges. This infolding proceeds in a posterior to anterior (inferior to superior, postnatally) direction according to the classic model of tracheoesophageal embryogenesis. Alternative theories depict a series of cranial and caudal folds along the evolving tracheoesophageal septum, and epithelial proliferation and apoptosis may play a role in the division of the trachea and esophagus as well (14). As the trachea is separating from the esophagus, the tracheal mesoderm is differentiating into C-shaped cartilage rings anterolaterally. Contrasting mesenchymal development occurs along the newly formed posterior tracheal wall where strips of smooth muscle are formed. The development of smooth muscle posteriorly and cartilage anteriorly at regular intervals is guided by differential expression of Fgf10 and Shh (15). Likewise, Fgf10 plays an essential role alongside Fgfr2 in the branching morphogenesis of the lung buds (13). By the end of intrauterine life, the trachea averages 5.7 cm in length, having 18 to 20 cartilaginous rings. Mesenchymal differentiation

within the esophagus results in a muscular layer of striated muscle in the upper one-third and smooth muscle in the lower two-thirds of the tube (16).

DIAGNOSIS

Prenatal Diagnosis of Aerodigestive Tract Disease

For many individuals, the diagnosis of aerodigestive tract disease begins in the prenatal phase. A "Triple Test" is available in the first trimester and combines a measurement of nuchal thickness on ultrasonography, maternal age, gestational age, and maternal serologic measurements of PAPP-A and beta hCG to predict the risk of trisomy 21, 18, and 13 as well as Beckwith-Wiedemann syndrome in the developing fetus (17,18). Second trimester screening can add serologic evaluation of inhibin-A and alpha-fetoprotein, constituting a "Penta test" which, when considered alongside the first trimester combined screening results, provides a more sensitive prenatal diagnosis of aneuploidy and neural tube defects (19,20). Invasive measures, such as chorionic villus sampling (CVS) in the late first trimester of pregnancy and amniocentesis in the second trimester, may identify individuals with chromosomal anomalies that place them at risk for postnatal problems, including aerodigestive tract dysfunction. Later in the second trimester of pregnancy, biometric measures of oral, oropharyngeal, and laryngotracheal structures can be obtained using four-plane sonography techniques. Individuals followed over time with ultrasonography demonstrate not only anatomic but also physiologic development, as increasingly complex orofacial, lingual, pharyngeal, and laryngeal movements indicate the evolution of suckling behavior. Further, children with genetic abnormalities identified through a Triple/Quad/Penta test, CVS, and/or amniocentesis demonstrate suckling dysfunction on prenatal ultrasonography compared to individuals without disease (21) (Fig. 87.3).

Because ultrasound is anatomical, physiologic, and noninvasive, it is currently the most important and commonly used means to diagnose aerodigestive disease prenatally. However, the application of fetal MRI is widening, and several reports exist documenting the utility of prenatal MRI in the diagnosis of aerodigestive tract anomalies that may predict respiratory embarrassment at delivery (Fig. 87.4). At many institutions, protocols are being developed to employ high-quality ultrasonography and fetal MRI in a complementary fashion to determine which patients should be offered *ex utero* intrapartum treatment (EXIT) to establish an airway (22). The utility of prenatal MRI likely will continue to evolve (23,24).

Postnatal Diagnosis of Aerodigestive Tract Disease: General Principles

As with any disease process, the diagnosis of congenital aerodigestive tract disease begins with a history and physical examination. Even in the management of an emergent airway obstruction, some modicum of historical information and physical observations guide the clinician to the appropriate urgent intervention. When evaluating a stable patient with congenital aerodigestive tract disease, a comprehensive history and physical examination may be obtained alongside flexible endoscopy and selected

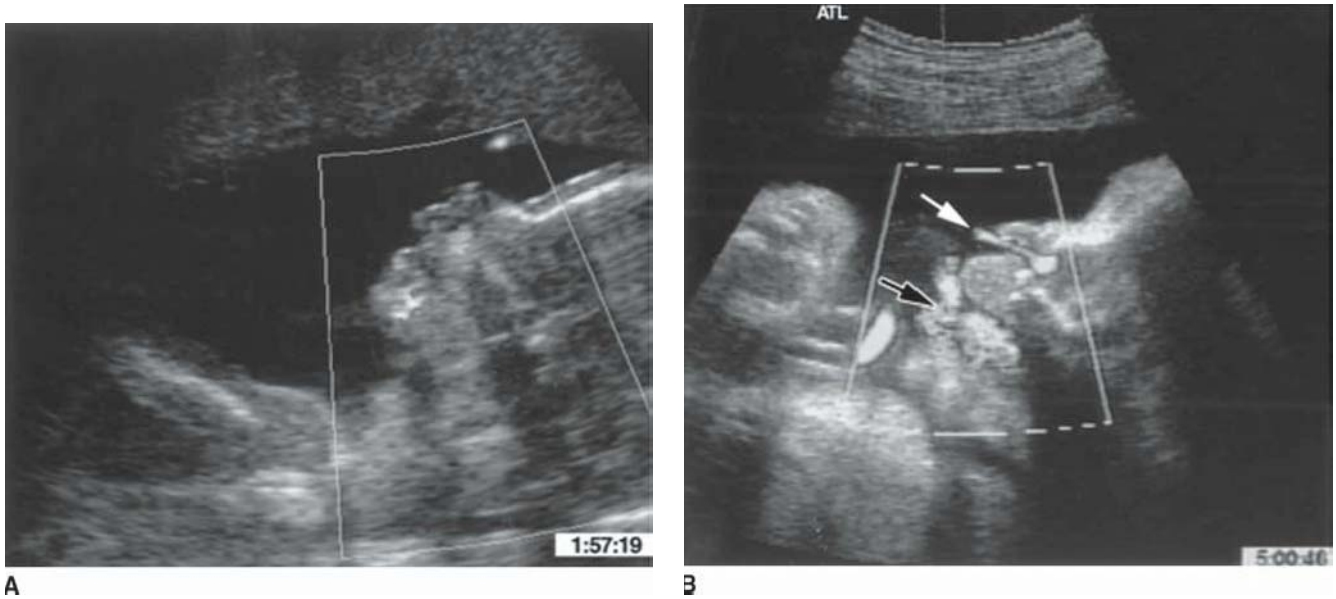

Figure 87.3 Parasagittal fetal ultrasound around 19 months depicting the fetus (**A**). Power Doppler imaging demonstrates amniotic fluid flowing through the mouth and nose (**B**) during swallows (black arrow) and respiration (white arrow). From Miller JL, Sonies BC, Macedonia C. Emergence of oropharyngeal, laryngeal and swallowing activity in the developing fetal upper aerodigestive tract: an ultrasound evaluation. *Early Hum Dev* 2003;71(1):61–87, with permission.

imaging. In an unstable patient, diagnosis and management often occur at the same time in the operating room in the process of securing a safe airway.

The functions of the aerodigestive tract include breathing, feeding, and voicing. Aerodigestive disease frequently affects more than one of these functions simultaneously, and a useful history not only focuses in on the diagnosis but also accounts for the variety and degree of disabilities the patient is experiencing. Noisy, rapid, and/or labored breathing is representative of respiratory dysfunction. Adventitious breath sounds include stertor, snorting, snoring/sonorous breathing, stridor, wheezing, and coughing. When these signs are present on inspiration, the airflow limitation is usually above the level of the vocal folds. Biphasic stridor is classically glottic or subglottic, while expiratory stridor originates below the larynx. The timing, severity, relapsing and remitting factors, effects of positional changes and effects on feeding must be clarified, and such useful historical information may be obtained from the family, nursing staff, respiratory therapists, speech pathologists and the primary physician team managing the patient. For safe feeding to occur, the infant must have a reasonably slow respiratory rate to allow suck–swallow–breathe coordination, and nasal breathing is required for this coordinated effort until around the eighth month of life. How breathing is affecting feeding, the technique (breast, standard bottle, specialized feeder/nipple) and position of feeding, the consistency of oral intake and any signs of choking, coughing, wet sounding respirations, desaturations, and the presence or absence of pneumonia are all important questions to ask. Spitting up and emesis are also important to ascertain, as retrograde esophageal movement may lead to aspiration of refluxate or point to a pharyngoesophageal anomaly. Finally, the quality, quantity, and volume of voicing must be determined.

The physical examination of the infantile aerodigestive tract must account for the unique craniofacial relationships in the infant. The head is relatively large while the neck is relatively small in circumference and short in length. The midface is flattened, and the retropalatal and retrolingual airspaces are relatively compressed compared to their adult counterparts (25). In fact, the tip of the epiglottis may touch the tip of the soft palate during deglutition, indicating the high position of the infant's larynx in the neck. The inferior margin of the cricoid cartilage is at C2 in the newborn and at C7 in the adult. With this in mind, the physical examination again focuses on the presence and degree of respiratory, feeding, and communication difficulties being experienced by the patient. The examination begins by noting the patient's color, body position, and apparent level of distress. Respiratory rate, effort, and sound are all noted, as are the presence, location, and severity of retractions. The presence of labored breathing with retractions is more serious than of loud breathing without effort or retractions. As less and less air movement occurs, the patient may become quieter as a consequence. The clinician should also note pulse oximetry data and whether the patient is receiving supplemental oxygen. The cry should be assessed for hoarseness, breathiness, or aphonia. Observing the infant during a feeding gives useful insight into suck–swallow–breathe coordination, signs of aspiration, and the overall safety of oral feeding.

The history and physical examination often point to the diagnosis of congenital aerodigestive tract disease, but additional diagnostics commonly are called upon to both confirm the diagnosis and stage the extent of comorbidities. A significant minority of patients have multiple congenital aerodigestive abnormalities (26). In a stable patient, after a detailed history and physical examination, a common next step is flexible nasopharyngoscopy and laryngoscopy. With an appropriately sized flexible scope (around 2.2 mm outer diameter or smaller), nasopharyngoscopy is well tolerated and safe without topical anesthetic (which might confound a flexible endoscopic evaluation of swallowing [FEES]). Flexible endoscopy allows the examiner to diagnose the nature of the disease, the level(s) of disease, and any dynamic airway collapse. The position of the patient matters in flexible nasopharyngoscopy. The larynx is best visualized when the patient is in a seated position as it allows the pharynx to open and the larynx to fall forward. However, neonates do not assume a seated position, and flexible endoscopy in their typical supine, side-lying or reverse-Trendelenburg position will best recapitulate obstruction and aerodigestive tract dysfunction as they experience it (Fig. 87.5). Concomitant administration of dyed liquids, purees, and solids allows the examiner to assess swallowing safety and dysfunction endoscopically (FEES). Importantly, what is seen on flexible endoscopy

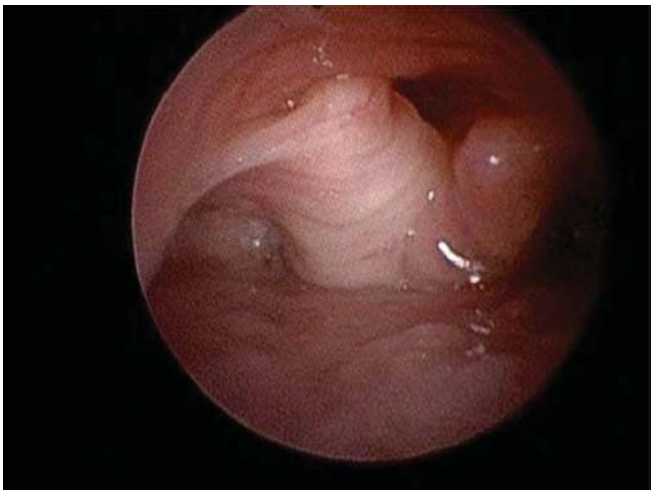

Figure 87.5 Flexible endoscopic view of the larynx in a supine infant demonstrating laryngomalacia secondary to bulky, obstructing supra-arytenoid tissue.

may also guide airway management when the patient undergoes treatment in the operating room.

In addition to flexible endoscopy, radiographic studies provide diagnostic and staging information in the stable patient. Plain films of the neck in anterior–posterior and lateral planes highlight the soft tissue relationships around the air column. However, most clinicians prefer the anatomical detail, multiplanar information, and surgical roadmap provided by computerized tomography (CT). Indeed, CT scanning is the initial imaging modality of choice for craniofacial, nasal, nasopharyngeal, oral, and oropharyngeal aerodigestive diseases (27–29). MRI also provides exceptional anatomical detail, but its added cost and absolute need for sedation render MRI less frequently employed. Dynamic radiographic studies continue to be useful in the diagnosis of aerodigestive diseases, and while airway fluoroscopy is of historical interest, cine MRI allows the clinician to determine anatomical levels of airway collapse under a plane of anesthesia that simulates sleep in patients with sleep-disordered breathing (30,31). Finally, a videofluoroscopic swallow study (VFSS or modified barium swallow study) remains an indispensable tool to diagnose dysphagia, make treatment recommendations, and occasionally directly see the effects of aerodigestive tract anomalies on swallowing (32).

Following an appropriate history and physical examination supplemented by appropriate imaging, rigid airway endoscopy is the gold standard in the diagnosis of aerodigestive tract disease. Nasal and nasopharyngeal lesions require nasal endoscopy/nasopharyngoscopy, whereas oral, oropharyngeal, hypopharyngeal, laryngeal, tracheobronchial, and esophageal diseases are diagnosed by microlaryngoscopy, bronchoscopy, and esophagoscopy. Diagnostic airway endoscopy requires careful preparation and adequate equipment to deal with expected and unexpected scenarios in the management of the patient's airway. The otolaryngologist must communicate with the anesthesia team their goals and expectations from the evaluation. Most rigid airway endoscopy in the operating room is performed with the patient anesthetized but spontaneously breathing. This allows a greater margin of safety as the patient is capable of unassisted gas exchange, and there is greater time to examine the airway before desaturation requires bagging or intubation. In this technique, topical anesthetic must be sprayed on the larynx and tracheobronchial tree to reduce laryngospasm and coughing. In neonates, 0.5% to 2% plain lidocaine typically is used. The exact technique of rigid airway endoscopy varies from surgeon to surgeon. Battery-powered intubation laryngoscopes (e.g., Miller, Phillips, or Wis-Hippel blade) and operating laryngoscopes with external light sources are both useful to examine the oral cavity, oropharynx, hypopharynx, and larynx. The operating laryngoscopes can be suspended for a two-handed stable examination and intervention as needed. Magnifying telescopes (Hopkins rod telescopes) are commonly used to enhance the examination and allow digital photo/video documentation. These scopes can be used independently with an intubation laryngoscope or with an operating laryngoscope. Alternatively, an operating microscope can be used with suspension laryngoscopy to evaluate and treat the larynx. Tracheobronchoscopy can be performed with a bare telescope passed through the glottis or with a ventilating bronchoscope containing a telescope. Advantages of the latter are obvious—the bronchoscope may be connected to the anesthetic circuit and the patient ventilated while the examination is taking place. However, the limiting factor in tracheobronchoscopy is the size of the patient's airway, and a much larger (and higher optical resolution) bare telescope can be passed into a small airway without the sheathing ventilating bronchoscope (Fig. 87.6). Operative rigid endoscopy is also the platform from which airway management, biopsies, and endoscopic therapies take place.

Postnatal Diagnosis of Aerodigestive Tract Disease: Specific Levels of Dysfunction

With an overview of aerodigestive disease diagnosis in mind, specific levels of aerodigestive tract dysfunction are detailed below. Key symptoms uncovered in a careful history, significant findings on physical examination, and other typical diagnostic results are highlighted.

Nasal and Nasopharyngeal

The symptoms and signs of nasal obstruction are sonorous or snorting inspiratory breath sounds with mild to moderate obstruction progressing to cyclic cyanosis relieved by crying and mouth breathing with complete nasal obstruction. Affected infants are poor feeders due to interruption of the suck–swallow–breathe mechanism. Voicing may be hyponasal. Flexible nasal endoscopy may note a tight anterior nasal valve secondary to congenital nasal pyriform aperture stenosis (CNPAS), an anomaly within the nasal passageway, or pooled secretions in the posterior

Figure 87.6 A 2.5 ventilating bronchoscope (**left**) and a 1.9 mm outer-diameter Hopkins rod telescope (**right**) can be mated to provide a magnified endoscopic assessment of the tracheobronchial tree. Alternatively, the telescope may be passed into the airway without the sheathing bronchoscope.

nasal passageway secondary to choanal stenosis or atresia. A high-resolution maxillofacial CT scan with axial, coronal, and sagittal reconstructions and/or three-dimensional (3-D) reconstruction is the single most useful radiographic study in the evaluation of congenital nasal anomalies because of its superior bony/soft tissue resolution (33,34). Rigid nasal endoscopy adds little to the diagnosis, but it is a platform from which both diagnosis and treatment can be instituted.

The symptoms and signs of congenital nasopharyngeal anomalies are largely the same as nasal ones. One exception is cysts or tumors (such as teratomas) that exert a mass effect on the nasal surface of the soft palate. In these instances, if the soft palate is stented open by a mass descending behind the palate, voicing is hypernasal secondary to velopharyngeal incompetence. If the entire nasopharyngeal space is obliterated, the cry is muffled. Again, flexible endoscopy is an indispensable diagnostic tool, especially as the scope tip can be rotated to evaluate all recesses of the nasopharynx, and a flexible nasopharyngoscope may be twisted through a stenotic choana. In these respects, flexible endoscopy is superior to rigid in the nasopharynx. As with nasal lesions, a high-resolution maxillofacial CT scan with axial, coronal, and sagittal

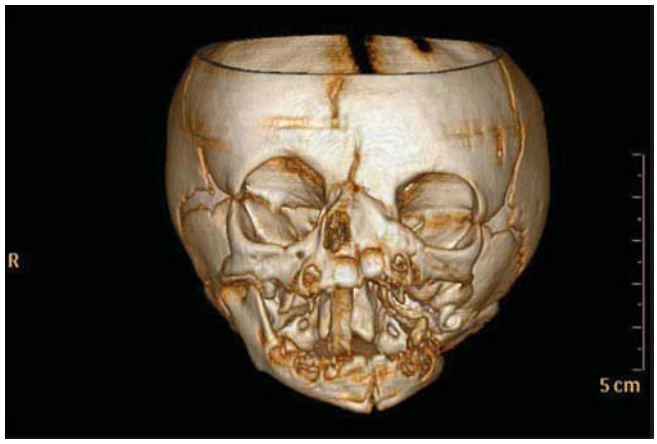

Figure 87.7 3-D reconstruction of a noncontrast-enhanced maxillofacial CT scan in a patient with unilateral left-sided hemiarhinia. A nasal trumpet is descending through the right nasopharynx.

reconstructions and/or 3-D reconstruction is the most useful radiographic study in the evaluation of congenital nasopharyngeal anomalies (Fig. 87.7) (33,34).

Oral

Congenital aerodigestive tract anomalies affecting the oral cavity are heterogeneous, ranging from abnormal bands, such as upper labial frenulum, ankyloglossia, and intergnathic bands, as seen in popliteal pterygium syndrome (35,36) to cleft palate to macroglossia, as seen in Beckwith-Wiedemann Syndrome (Fig. 87.8)

Figure 87.8 Beckwith-Wiedemann syndrome causing macroglossia in a neonate.

(37,38). The symptoms and signs of minor anomalous bands largely relate to feeding, as the inability to evert the upper lip or protrude the tongue may preclude effective breastfeeding. Airway and voicing are unaffected. Similarly, cleft palate (without micrognathia and/or relative macroglossia) is mostly a feeding problem at birth. In contrast, microstomia, intergnathic bands, micrognathia with relative macroglossia, absolute macroglossia and intraoral tumors produce drooling, gasping during feeding, muffled cry, and obstructed breathing patterns. When no oropharyngeal obstruction is present, quiet breathing through the nose may be unaffected. Nasopharyngoscopy rules out oropharyngeal extension, but the majority of the salient physical exam can be accomplished through direct observation with a tongue depressor and a headlamp. Consistent with the heterogeneous nature of congenital oral anomalies, there is no single imaging modality that is required or preferred for diagnosis. When the physical examination alone is insufficient, mandibular or dentigerous anomalies may be evaluated best with a panorex. Relationships between the upper and lower jaws and the encompassed soft tissue are best shown on a maxillofacial CT scan, while intrinsic soft tissue lesions (such as lingual masses) achieve best delineation on MRI (39). For vascular malformations, MRI adds the benefit of vascular phases that provide additional diagnostic sensitivity (MR angiography [MRA] and MR venography (40)).

Oropharyngeal

Moving inferiorly, the oropharyngeal space becomes the common aerodigestive tract in the nasal-breathing neonate. Symptoms and signs of congenital oropharyngeal anomalies include wet stertorous breath sounds, inspiratory stridor, snoring, gasping, discomfort and possibly cyanosis with feeding, and a muffled cry. Patients often breathe better in the prone position (which is also true for patients with stridor of a supraglottic etiology). Aspiration is likely with larger lesions due to suck–swallow–breathe interruption. Flexible endoscopy is essential to the diagnosis of oropharyngeal congenital anomalies because it provides a dynamic assessment of breathing, the management of secretions, and any effects the oropharyngeal lesion is exerting on the larynx—particularly with vallecular cysts that tend to drive the epiglottis into the glottic inlet (41). With oropharyngeal lesions, imaging may not be necessary. Important relationships to define are mostly soft tissue relationships, and MRI provides the best resolution. However, increased speed, decreased cost, and the possibility of avoiding sedation often support the use of a contrast-enhanced CT, which provides adequate anatomic delineation, particularly for cystic anomalies. Both for diagnosis and for airway management, rigid microlaryngoscopy and bronchoscopy are indicated if the oropharyngeal lesion abuts the larynx/hypopharynx.

Hypopharyngeal/Laryngeal

Anomalies of the hypopharynx produce dysphagia, muffled voicing, and airway obstruction by interfering with the esophageal inlet and/or the patency and movement of the larynx. Stridor is inspiratory, and the abnormal collection of hypopharyngeal secretions may lead to wet sounding respirations. Similarly, a large lesion of the hypopharynx, which directs secretions and oral intake into the larynx, produces coughing and aspiration. Flexible endoscopy is essential to diagnose the lesion and to assess its dynamic effects on the management of secretions, swallowing, and breathing. As with oropharyngeal lesions, imaging may be unnecessary, but a contrast-enhanced CT and MRI both provide adequate anatomic detail to resolve hypopharyngeal lesions. Dysphagia is common with hypopharyngeal anomalies, and VFSS is necessary to complete the workup in most instances (Fig. 87.9) (32). Microlaryngoscopy, bronchoscopy, and esophagoscopy complete the evaluation, and postcricoid lesions are evaluated specifically by lifting the larynx with the laryngoscope blade during a comprehensive exam.

The larynx has three cardinal functions: (a) an airway protection mechanism during swallowing, (b) a respiratory conduit, and (c) a phonatory source. These functions are carried out over a relatively small area, and their success depend on intact sensation and movement (glottic abduction, adduction, and laryngeal elevation), laryngeal patency, and the ability of thin, crisp vocal folds to be pulled together and driven by an adequate subglottic air column. The symptoms and signs of aerodigestive disease in the

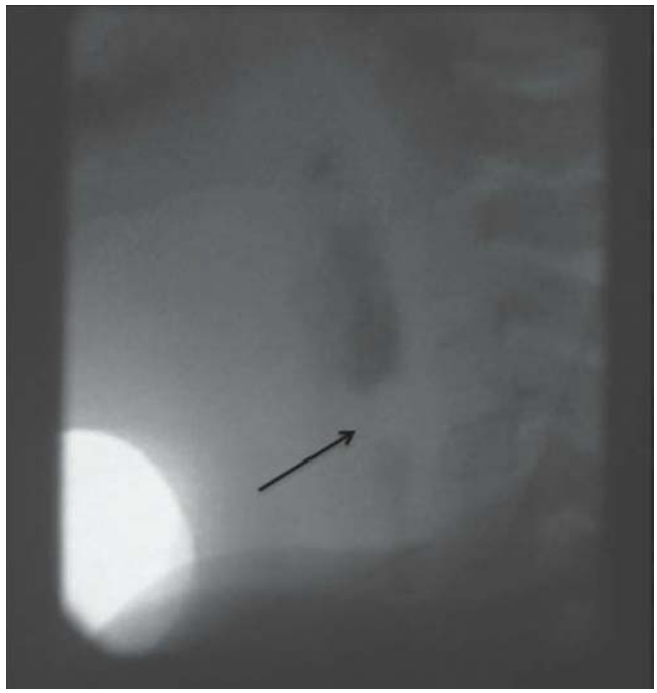

Figure 87.9 Sagittal video-fluoroscopic swallow study demonstrating bolus restriction by a cricopharyngeal bar (*arrow*) in the hypopharynx. Image courtesy of Gwen Provo-Bell, M.S., SLP-CCC.

larynx include dysphagia and aspiration with or without coughing and recurrent aspiration pneumonias. Stridor is present and is classically described as inspiratory when the lesion is supraglottic or glottic and biphasic when the lesion is subglottic. Stridor may progress to retractions and cyanosis. When stridor is absent at birth but appears in the first few weeks or months of life, laryngomalacia is the most likely cause, although subglottic hemangiomas also usually present with some delay. Vocal dysfunction due to laryngeal disease may be muffled or coarse if there is a large supraglottic lesion, hoarse, breathy, or aphonic if the disease is glottic, and hoarse and breathy if the disease is subglottic.

Ancillary diagnostic techniques are important in the workup of congenital laryngeal disease. Flexible laryngoscopy is indispensable, and the examiner should note pooling of secretions (denoting sensory dysfunction or a mass) (42), masses, tracts or mucosal abnormalities or vocal fold movement abnormalities. The examiner should attempt to differentiate between a fixed or neurologically paralyzed glottis and a glottis restricted by scarring. Vocal folds resting in a paramedian position may be paradoxically drawn inwards during inspiration. In contrast, expiratory adduction of the vocal folds or medial rotation of the supraglottic larynx suggests that motor input is intact. Dynamic collapse of the larynx with respiration should be noted as well. If possible, the subglottis should be assessed for stenosis, mucosal changes (cysts, inflammatory changes, exudates) and for masses, such as a subglottic hemangioma. Some authors routinely pass the flexible nasopharyngoscope through the vocal folds to obtain an anatomical and dynamic view of the trachea as well (43), although many voice concerns for laryngospasm, desaturation, and patient distress. A FEES exam adds an important dimension to flexible laryngoscopy, and patients with laryngeal dysfunction may demonstrate laryngeal penetration, aspiration, and hypopharyngeal residue (44). With FEES, the examiner is also able to ascertain whether the patient's unique laryngeal anatomy contributes to or protects against dysphagia and aspiration, potentially valuable in surgical planning. A VFSS provides complementary data, and all patients with congenital laryngeal disease benefit from this functional radiographic exam. Plain films of the neck in posterior-anterior and lateral planes remain useful to quickly diagnose swelling or mass effects in the larynx and particularly the subglottis. However, the phase of respiration must be considered, as an adducted glottis may masquerade as a swollen and inflamed conus elasticus on PA views—the so-called steeple sign. If greater anatomical detail is needed, one must recall that the neonatal larynx is nonossified. Therefore, MRI provides the best resolution of intrinsic laryngeal disease. However, CT scanning is less expensive, faster, and may not require sedation. The anatomical detail on CT is good, and contrast can be added to highlight inflammatory lesions such as saccular cysts and third or fourth branchial arch anomalies that may surround the larynx. With the exception of mild laryngomalacia, most congenital aerodigestive tract diseases affecting the larynx are best evaluated by rigid microlaryngoscopy and bronchoscopy (Fig. 87.10). Clear advantages over flexible endoscopy include improved optical resolution, the ability to splay the posterior glottis in the search for a laryngeal cleft, and the ability to palpate the cricoarytenoid joints and interarytenoid space in the case of vocal fold movement abnormalities. The subglottis may also be completely evaluated and sized during a rigid endoscopic evaluation.

Tracheobronchial and Esophageal

When considering the diagnosis and management of congenital tracheobronchial and esophageal disease, one must consider the benefits of a multidisciplinary approach. Many of the larger children's hospitals around the globe use multispecialty clinics involving otolaryngology, gastroenterology, pulmonology, speech pathology (to assess both voicing and swallowing), and others to provide comprehensive, concentrated diagnosis, and management of aerodigestive tract diseases (32). While the tracheobronchial tree and the esophagus remain under the purview of the otolaryngologist, the other specialists possess unique equipment, training, and perspective to supplement the evaluation and to benefit the patient.

The symptoms and signs of tracheobronchial dysfunction pertain more to airway limitation than problems with swallowing or voicing, although safe feeding may become difficult with labored breathing. Patients exhibit expiratory stridor that may be accompanied by increased use of intercostal musculature. Mild, though significant, tracheomalacia may resemble reactive airways disease (asthma), and infants may be placed unnecessarily on bronchodilators that tend to increase respiratory rate and effort. With agitation, the stridor of tracheomalacia becomes worse because the trachea is being collapsed by thoracic compression, and it is being drawn together by an increasingly fast column of air moving out of the bronchi. In these conditions, stridor may progress from an expiratory wheeze to a coarse, honking sound. Reflex apnea results from complete tracheal collapse (45). Tracheal stenosis secondary to complete tracheal rings tends to be less dynamic. The tracheal lumen is extremely small, and the adhesive property of water in the saliva coats the airway and enhances obstruction. Respirations are usually wet sounding in both the inspiratory and expiratory phases with labored breathing and low-normal oxygen saturations. Flexible endoscopy to the level of the glottis rules out concomitant laryngomalacia or vocal fold immobility. Plain films of the trachea may demonstrate congenital stenosis or tracheomalacia, or both. However, an inspiratory film of a patient with tracheomalacia is usually normal in appearance. Newer dynamic imaging protocols using multidetector CT and cine MRI can capture and quantify dynamic collapse of the airway (30,46). Additional advanced imaging modalities are high-resolution CTA or MRA, which

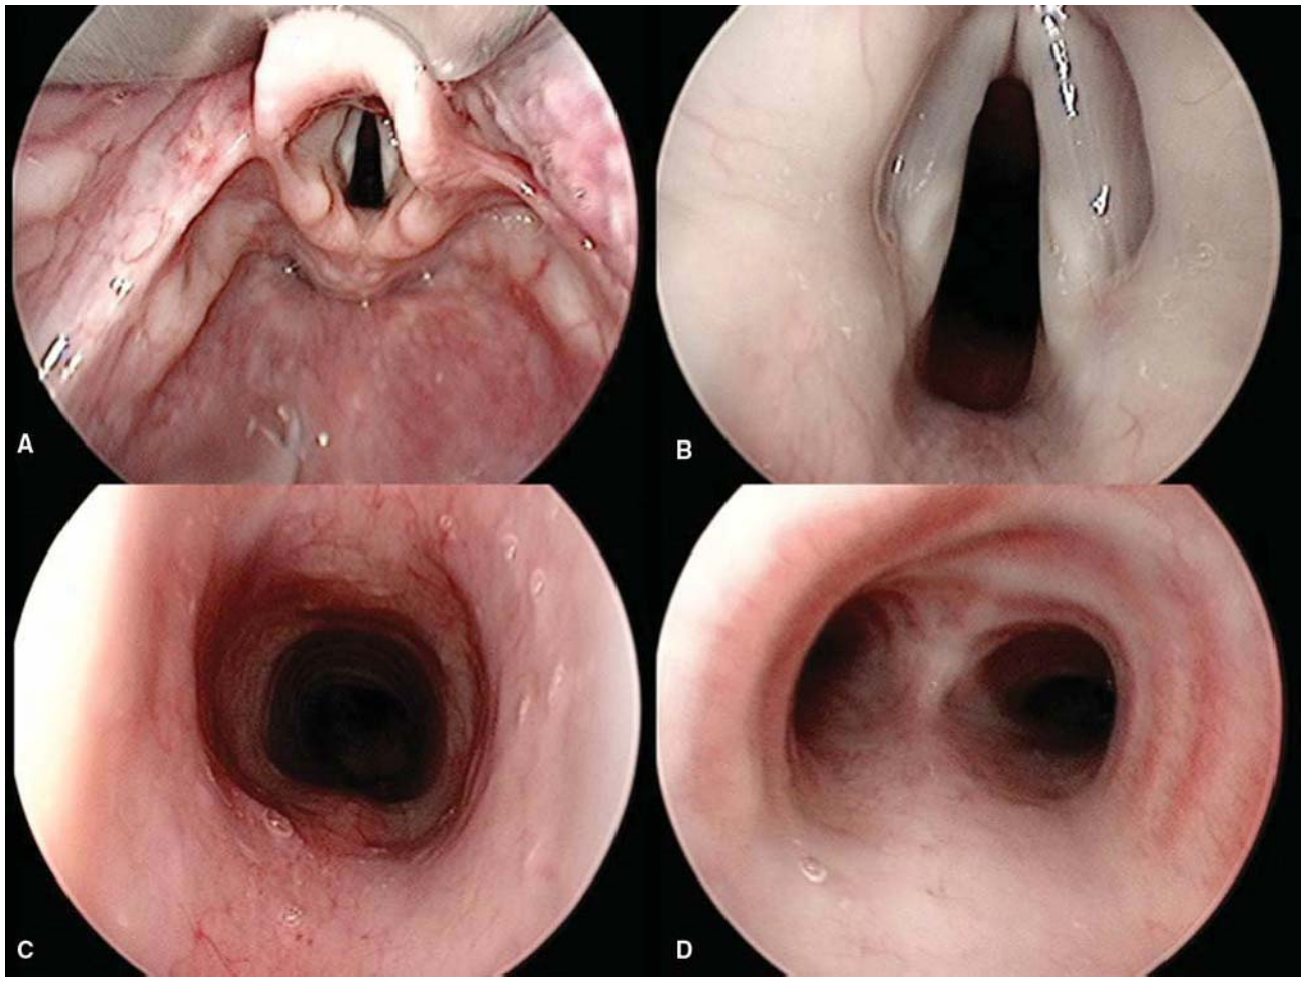

Figure 87.10 Endoscopic photos of the supraglottic larynx (**A**), glottis (**B**), subglottis (**C**), and trachea (**D**) in a 2-year-old without airway pathology in whom an airway foreign body was being excluded. Normal anatomy is seen throughout.

demonstrate the low cervical and mediastinal vascular anatomy surrounding the trachea. Either of these studies can delineate tracheomalacia secondary to innominate artery compression, aortic compression, vascular rings, a pulmonary artery sling, or some combination thereof, and further surgical therapies such as aortopexy may be guided by these findings (47). Additionally, congenital tracheal stenosis secondary to complete tracheal rings is frequently associated with mediastinal vascular anomalies that may require simultaneous repair (48). A final benefit of CTA or MRA is the demonstration of complete tracheal rings provided on 3-D reconstruction. Rigid tracheobronchoscopy is required to confirm the diagnosis of congenital tracheal anomalies, but as alluded to earlier, flexible bronchoscopy under a spontaneous ventilatory plane provides complementary and highly useful information about dynamic airway lesions, such as tracheomalacia and bronchomalacia (Fig. 87.11). Often, the pulmonology service performs this evaluation in the same operating room setting, and bronchoalveolar lavage is simultaneously performed to diagnose inflammatory pathologies.

Congenital esophageal diseases may be due to intrinsic abnormalities in the esophageal lumen, developmental arrest, external mass effects, or problems with tracheoesophageal separation (16). Partitioning abnormalities along the tracheoesophageal septum, such as

Figure 87.11 Rigid endoscopy demonstrating tracheomalacia secondary to vascular compression imposed by the innominate artery in an infant.

a laryngotracheoesophageal cleft or tracheoesophageal fistula (TEF), potentially interfere with both feeding and respiration. Classically, the affected infant may choke with feeding with clefts and fistulas, and gastric distention with air may occur with certain types of fistulas. With time, failure to thrive, aspiration pneumonia and bronchiectasis occur. H-type TEFs produce the subtlest symptoms. In contrast to tracheoesophageal problems, there are a variety of intrinsic esophageal abnormalities. A cricopharyngeal bar produces dysphagia and aspiration with rapid swallowing sequences or immediate regurgitation, whereas esophageal diverticula produce delayed rumination. Awake flexible nasoesophagoscopy has not been utilized in the evaluation of infants and children, and radiographic evaluations are the most useful ancillary studies. A contrast-enhanced esophagram (barium swallow) demonstrates the anatomy within or impinging upon the esophageal lumen. A VFSS adds to this a real-time sagittal and coronal assessment of swallowing from the oral cavity to the stomach. Not only does VFSS assess the various phases of swallowing, but it also allows evaluation of the effects of consistency modification in the patient with dysphagia (32). When an extra-esophageal mass or diverticulum is suspected based on contrast-enhanced esophagram or VFSS, a contrast-enhanced CT or MRI provides excellent anatomical detail and clearly demonstrates mediastinal vascular anatomy. Both rigid and flexible esophagoscopy provide direct assessment of the esophageal lumen and allow biopsies to be taken. In the multidisciplinary model of aerodigestive disease diagnosis, a pediatric gastroenterologist performs esophagogastroduodenoscopy.

TREATMENT

General Principles of Treatment

The following section highlights select congenital aerodigestive tract anomalies, their embryology, presentation, diagnosis, and treatment. Congenital aerodigestive diseases often produce dysfunction in more than one realm of the aerodigestive tract. Accordingly, any treatment rendered must account for its impact on feeding, breathing, and voicing. Sometimes, treatment in one area improves function in other areas, but the opposite may be true. As an example, improving voicing by vocal fold medialization also improves swallowing by closing an incompetent glottis. However, closing the glottis renders the respiratory conduit smaller, and dyspnea may ensue. In contrast, correcting choanal atresia improves nasal respiration and allows the suck–swallow–breathe sequence to be optimized. Voicing is only subtly affected as hyponasality improves. The treating physician must bear in mind these principles when managing unique aerodigestive problems. The specific disorders detailed below serve as a guide, and their treatment principles may be extrapolated to less common disorders.

Figure 87.12 Transoral view of a hemangioma involving the left hemipalate in an infant with mild feeding difficulties.

Nasal and Nasopharyngeal

Pyriform aperture stenosis obstructs the nasal airway anteriorly, and choanal stenosis or atresia obstructs it posteriorly. In the nasal space between the pyriform aperture and the choana, a variety of intranasal masses creates airflow resistance. These include nasolacrimal duct cysts, which are treated by endoscopic marsupialization, hemangiomas (Fig. 87.12), nasolabial cysts, and defects of the anterior neuropore that lead to dermoids, gliomas, and encephaloceles. Masses intrinsic to the nasal passageway should be approached sublabially or endoscopically if the pathology of the congenital mass is benign and medical management (including propranolol for hemangiomas) has failed (49,50). The anterior neuropore lesions all require surgical management that includes resection of the descending mass. Because a concomitant anterior skull base repair may be necessary (51,52), the opinion of an experienced neurosurgeon is valuable prior to undertaking resection of an anterior neuropore defect from a solely endoscopic approach. The management of nasal pyriform aperture stenosis and choanal atresia is described below.

Congenital Nasal Pyriform Aperture Stenosis

CNPAS is a rare anomaly that occurs secondary to bony overgrowth of the nasal process of the maxilla, and it is frequently accompanied by a solitary median maxillary central incisor (SMMCI) (53,54). While CNPAS may occur in isolation, hypertelorism, a flat nasal bridge, and the central mega-incisor are clinical features of premaxillary dysgenesis associated with holoprosencephaly (55). Pituitary disorders and dental and facial anomalies also are part of this spectrum. The pyriform aperture is the narrowest part of the nasal cavity, and small changes in the cross-sectional area significantly affect airflow. Newborns present with symptoms of snorting, gasping, and respiratory distress that are

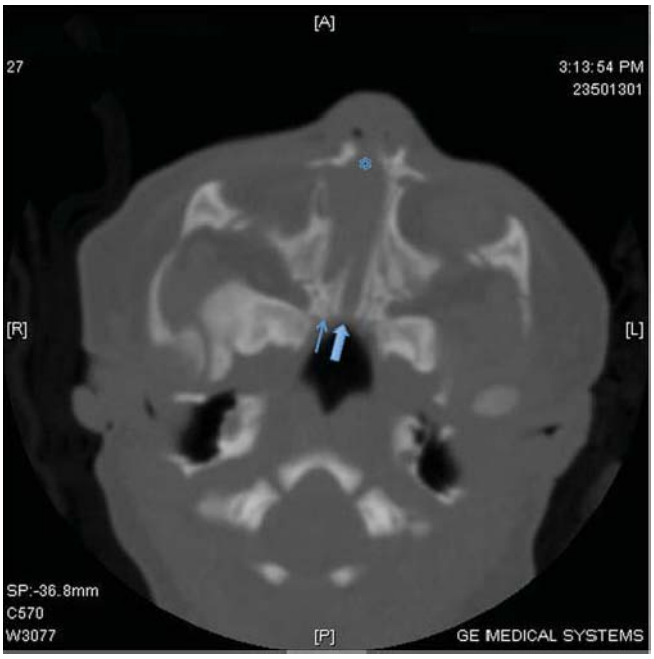

Figure 87.13 Maxillofacial CT in the axial plane without contrast demonstrating CNPAS (*asterisk*) and choanal atresia that is bony on the right side (*small arrow*) and bony-membranous on the left side (*large arrow*).

relieved by crying. Failure to pass a nasopharyngeal catheter may result in a misdiagnosis of choanal atresia. The diagnosis of CNPAS is established by physical examination and is confirmed by a maxillofacial CT (Fig. 87.13). At the level of the inferior meatus, the intermaxillary width is normally greater than 10 mm; a distance less than 8 mm strongly suggests CNPAS (56). By contrast, the height of the nasal cavity and cross-sectional area of the choana are not altered. If a SMMCI is discovered on imaging, a complete endocrine workup should be considered due to the risk of concomitant pituitary dysfunction (55). Nonoperative management begins with topical vasoconstrictive drops and/or intermittent use of a nasal trumpet. If the patient remains symptomatic, definitive repair is accomplished through a sublabial approach that exposes the inferior and lateral pyriform aperture. The bony space is enlarged with a drill, taking care to avoid damage to the maxillary tooth roots. The need for postoperative stenting up to 4 weeks is variably reported in the literature, though some stent only long enough for the skin flaps to be established again (54,57–59). As with stents placed at any level in the aerodigestive tract, granulation tissue may form beneath and at the ends of the stent. Systemic steroids, topical steroids, antibiotics, saline rinses, and mitomycin-C application are employed as indicated to reduce granulation and subsequent scar propagation.

Choanal Atresia and Choanal Stenosis

Choanal atresia results from failure of the nasobuccal membrane to recanalize in the embryonic phase of intrauterine development. The resulting atresia is either bony (around 30%) or a mixture of bony and membranous tissue (around 70%) (33). If the nasobuccal membrane recanalizes incompletely, choanal stenosis results. Two-thirds of choanal atresia is unilateral. If bilateral disease is encountered, there is a 75% chance that other congenital anomalies will be discovered, including anomalies that make up the CHARGE (coloboma, heart defect, atresia of the choana, retardation of growth and development, genitourinary anomalies and ear abnormalities) syndrome (60). Mutations in the CHD7 gene (8q12.2) cause more than half of CHARGE cases (4). Patients with unilateral choanal atresia or choanal stenosis have snorting and labored breathing that is improved with crying. The presentation of these conditions may be delayed and include mouth breathing, recurrent sinusitis, chronic rhinorrhea, otitis media, and speech problems. In contrast, bilateral choanal atresia presents at birth with agitation progressing to cyclic cyanosis that is relieved with crying. On anterior rhinoscopy, the occluded nasal cavity is typically filled with thick, tenacious secretions. The inability to pass a 6 Fr catheter beyond 3 cm into the nose raises the possibility of choanal atresia, and flexible endoscopy after suctioning confirms a blind-ending nasal passageway. A maxillofacial CT scan with axial, coronal, and sagittal reconstructions clarifies the type of atresia (bony or bony-membranous) or stenosis, the thickness of the lesion, and its relation to the overlying skull base (33,34). Specifically, a choanal space that is less than 6 mm across in the coronal plane is consistent with choanal stenosis (61). Complete blockage indicates atresia (Fig. 87.14).

Figure 87.14 Maxillofacial CT in the axial plane without contrast demonstrating right-sided choanal atresia and left-sided choanal stenosis.

Choanal stenosis may be managed with topical vasoconstrictive agents, dilation, and/or nasal trumpets, while bilateral atresia requires a formal repair. Unilateral atresia also requires formal repair, but topical vasoconstrictive agents and other less-invasive measures in the nonatretic passageway may allow unilateral atresia repair to be postponed for some time. Historically, transpalatal techniques were used to canalize the nasal passageways with a drill (62). Interference with palatal growth as well as palatal fistula is a concern with this approach. Currently, most surgeons opt for transnasal endoscopic repair whenever nonoperative measures fail—immediately for bilateral choanal atresia and within the first few months of life for unilateral atresia (63). Endoscopic repair begins with perforation of a thin portion of the atretic plate with urethral sounds, followed by sequential rigid or balloon dilation and resection of the posterior vomer. The intruding pterygoid plates, which are the lateral bony boundaries of the stenosis, may be reduced with a drill. Remaining inferior to the posterior end of the middle turbinate reduces the risk of skull base violation. Postoperative stenting for up to 6 weeks is reported in the literature (Fig. 87.15) (64–66).

Oral

Because of the heterogeneity of tissues found in the oral cavity (epithelial, salivary, dental, special sensory, muscular, and bony), congenital oral lesions take on many forms. Suprahyoid venolymphatic vascular malformations commonly affect the floor of mouth, and the treatment algorithm for such vascular malformations depends on the size of the constituent cysts and their location (64–66). A discussion of gnathic and odontogenic conditions is beyond the scope of this text. One common condition, ankyloglossia, and one representative mass, lingual choristoma (foregut duplication cyst), are examined below.

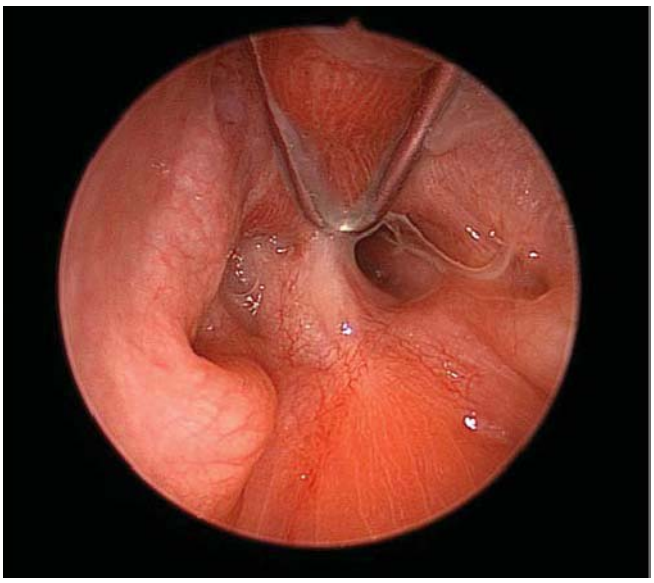

Figure 87.15 A 120-degree endoscopic view of the atretic choana in the same patient.

Ankyloglossia

Ankyloglossia, or tongue-tie, is a first branchial arch anomaly that results from persistence of the embryologic band connecting the anterior tongue with the medial surface of the developing mandible (67). A variation of ankyloglossia known as "posterior tongue tie" represents a densely adherent genioglossus. In this case, the problem is posterior and submucosal to the typical thin anterior band causing tongue restriction. Symptoms of ankyloglossia are poor feeding, particularly breastfeeding, in infancy and articulation problems in childhood. Respiratory symptoms are nil. The diagnosis is made by lifting the tongue from the floor of mouth and pulling it forward. If the tongue cannot protrude at least 2 mm beyond the mandibular alveolar ridge (or mandibular incisors) and/or if the tongue cannot contact the palate, treatment is warranted (5). A posterior tongue-tie is diagnosed by palpating the ventral midline tongue attachment for a dense, shortened band anchoring the tongue to the floor of mouth in an infant with feeding difficulty. In the neonate or young infant, a frenulectomy is performed at the bedside or in the office with proper patient restraint. Local anesthetic can be topically applied (benzocaine jelly) and infiltrated into the midline floor of mouth and midline ventral tongue (0.5% lidocaine with epinephrine 1:200,000). The frenulum is cross-clamped with a straight hemostat and sharply divided. Some surgeons will suture the wound. A posterior tongue-tie is treated by cross-clamping the tight band on the ventral tongue. The band is divided by dissecting into the ventral attachment until the tongue becomes mobile and a diamond-shaped wound is produced (68,69). Recurrence of ankyloglossia is relatively rare.

Lingual Choristoma

Lingual choristomas are sometimes termed "foregut duplication cysts," and the variable lining of the cysts may belie a heterogeneous origin (5,70). When gastric mucosa is found within the cyst, the pathophysiology may be heterotopic gastric tissue buried within the developing tongue (71). Alternatively, several authors propose that lingual choristomas are a duplication of the foregut with early arrest in development and secondary incorporation by the tongue. The cysts from two patients analyzed by Burkart et al. (72) were lined by a squamous epithelium with foci of dermal appendages and lymphatic tissue that pointed to a branchial origin, recalling that the tongue is formed anteriorly by fusion of first arch mesenchyme and posteriorly by arches 2 to 4. The symptoms and signs of lingual choristoma are those of any lingual mass, and the differential includes dermoid cyst, lymphatic or venolymphatic vascular malformation, hemangioma, teratoma, mucocele, ranula, epidermoid cyst, and lymphoepithelial cyst (70). The mass may produce symptoms ranging from

none to obstruction of the oral cavity with inability to handle secretions and poor suck–swallow–breathe coordination. On physical exam, the tongue may demonstrate a mass or submucosal asymmetry. Large masses force the tongue posteriorly and superiorly toward the oropharynx. Movement may be impaired. Flexible nasopharyngoscopy is important to delineate any concomitant oropharyngeal obstruction or glossoptosis that may alter airway management, and a nasal trumpet will offer significant relief in these circumstances. The oral cavity lends itself to physical diagnosis, but for any deep mass a contrast-enhanced CT or MRI provides the necessary anatomical detail. Lingual choristomas are fluid filled and concentrate contrast on CT or appear bright on T2 weighted MRI (Fig. 87.16) (39,72). The management of most lingual masses is surgical, although macrocystic lymphatic malformations are amenable to sclerosis (73). Choristomas always are managed surgically to correct the anatomical defect to confirm benign pathology. If the lingual mass effect is significant, flexible transnasal intubation in the operating room is a convenient means to secure the airway. Most oral tongue choristomas occur near the ventral reflection of the tongue onto the floor of mouth, and the incision is placed at this reflection (72). Midline masses may be approached through a midline glossotomy. In all approaches, care must be taken to avoid damage to the lingual nerve, the submandibular duct, and the lingual artery on either side of midline. The prognosis is good for a fully excised lingual choristoma.

Oropharyngeal

Vallecular cysts, lingual thyroid tissue, and lingual thyroglossal duct cysts are fairly common congenital oropharyngeal lesions. Teratomas, vascular malformations, and hemangiomas have been described here as well (74). Because most congenital oropharyngeal lesions exert mass effect, all require some operative treatment with the exception of a small to moderate sized hemangioma, which might respond satisfactorily to propranolol or other systemic therapy (49). Prior to resecting lingual thyroid tissue, a careful investigation should be made for the presence of thyroid tissue in the neck (75,76). The management of vallecular cysts is detailed below.

Vallecular Cyst

Vallecular cysts are mucus retention (pseudo)cysts or, more commonly, respiratory epithelium-lined cysts that develop in the vallecular space in infancy (41). The most common presenting signs and symptoms are stridor or respiratory distress, or both, because the mass is forcing the epiglottis into the laryngeal inlet. The anterior–posterior dimension of the tongue base is functionally enlarged and less sensate, and dysphagia and aspiration are common findings. Respiratory distress also leads to feeding difficulties (41,77). Flexible nasopharyngoscopy is the simplest means to diagnose a vallecular cyst. From this vantage, a slightly eccentric, smooth, yellowish, bluish, or gray mucosalized mass is seen in the vallecular space (78). When the

Lingual cyst lined by squamous epithelium. *Int J Pediatr Otorhinolaryngol* 2005;69(12):1649–1653, with permission.

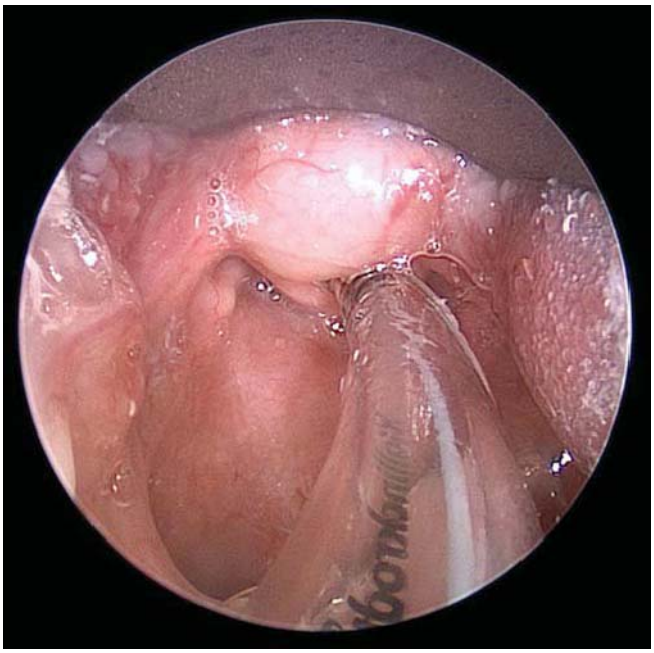

Figure 87.17 Endoscopic view of a vallecular cyst in an infant seen at intubation.

diagnosis is certain, radiologic exams are unnecessary. Sagittal CT or MRI is sensitive, specific, and useful to image recurrent lesions. Rigid endoscopy in the operating room is essential. It confirms the diagnosis and provides a safe means of securing the airway, which is often deranged by the cyst (Fig. 87.17). Because vallecular cysts drive the epiglottis posteriorly to occlude the endolarynx, intubation can be difficult. Definitive management requires surgical excision or marsupialization (41,77,78). Simple needle aspiration is associated with an unacceptably high risk of recurrence but may be necessary acutely if respiratory distress develops, especially during induction of anesthesia.

Hypopharyngeal and Laryngeal

The most common causes of stridor in the newborn are frequently listed as laryngomalacia, vocal fold immobility, and congenital subglottic stenosis. The onset of symptoms attributable to laryngomalacia usually begins a few weeks after birth. With appropriate gastroesophageal reflux disease (GERD) management and time, most patients do not require surgical treatment (26). When supraglottoplasty is indicated to resolve laryngomalacia, a variety of techniques exist including a laser, microlaryngeal instruments, or a microdebrider. Overall, results are good. Vocal fold immobility may be unilateral or bilateral. In the patient who fails expectant management (including GERD therapy), treatment depends on two factors (a) the type of immobility present—neurologic (including paralysis associated with Arnold-Chiari malformations) (79), cricoarytenoid joint fixation or restriction secondary to interarytenoid scarring, and (b) whether the immobility is unilateral or bilateral.

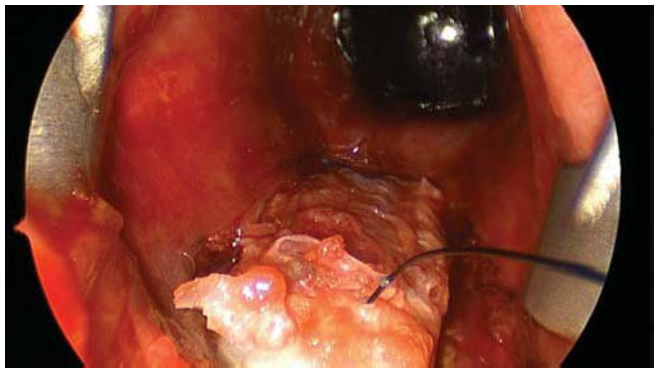

Figure 87.18 Endoscopic view of a posterior costal cartilage graft being placed endoscopically to relieve posterior glottic stenosis. The blue suture is a control suture that remains attached until the graft is placed and requires no additional manipulation.

Bilateral vocal fold immobility is the most symptomatic, and definitive management includes endoscopic cordotomy, arytenoidectomy or arytenoidopexy (endoscopic or open), vocal fold lateralization, or posterior glottic cartilage grafting (with endoscopic or open graft placement) (Fig. 87.18) (80–83). Congenital subglottic stenosis is one-tenth as common as acquired subglottic stenosis. In symptomatic patients, endoscopic incision and balloon dilation is usually attempted first (84), with anterior and/or posterior cartilage grafting or cricotracheal resection reserved for difficult or refractory stenoses (85). Subglottic hemangiomas can cause stridor in an infant, and frequently the subglottis is intrinsically narrow in these patients, even after resolution of hemangiomatous disease. Propranolol has emerged as an initial therapy for subglottic hemangiomas (12,86,87). Other therapies include submucosal injection of steroids, systemic steroids, laser ablation, and open excision with concomitant laryngotracheoplasty. Any congenital laryngeal anomaly that results in significant morbidity may be managed initially with a tracheotomy until other treatment options are appropriate. Additional consideration is given below to the management of laryngeal clefts and webs.

Laryngeal Cleft

Complex folding and inward movement of lateral mesodermal ridges from inferior to superior separates the trachea from the esophagus. Superior arrest leads to a laryngotracheoesophageal (laryngeal) cleft. This anomaly may occur in isolation or in association with other anomalies, such as Pallister-Hall syndrome (88), Opitz-G syndrome (88), and VATER/VACTERL association (12,89). Laryngeal clefts produce aspiration secondary to a persistent channel between the esophagus posteriorly and the airway anteriorly during swallowing. If the cleft margins are composed of floppy excess mucosa, some degree of airway obstruction results. Voicing may be impaired from turbulent airflow and from accumulation of secretions around the glottis. Flexible laryngoscopy usually demonstrates medialized

arytenoids with a suspicious trough between them, but rigid microlaryngoscopy and bronchoscopy are required to diagnose a laryngeal cleft. In this setting, the interarytenoid space can be spread and palpated. The distal extent of the cleft can be measured. Static radiographic examinations add nothing to the diagnosis of a laryngeal cleft, but a VFSS is indispensable. This examination diagnoses aspiration secondary to laryngeal incompetence as well as other levels of swallowing dysfunction and determines what consistencies may be taken safely by mouth. In a patient with chronic aspiration, a high-resolution chest CT may demonstrate bronchiectasis. Laryngeal clefts are categorized most commonly using the Benjamin-Inglis Classification (90), where a type I cleft constitutes a deep interarytenoid notch without posterior cricoid involvement; type II clefts extend into but not through the cricoid; type III clefts extend through the cricoid plate and into the cervical trachea, and type IV laryngeal clefts extend into the thoracic trachea or even into a bronchus. Management of type I and type II laryngeal clefts begins with GERD treatment and dietary modification to produce feedings of an appropriately thick consistency. When dietary modification fails or with type III (Fig. 87.19) or type IV clefts, operative management is required (91–93). Some authors report that good temporary disease control with type I laryngeal clefts can be achieved with gelfoam injection into the posterior interarytenoid space (94). Endoscopic suture closure of the cleft may be attempted if the patient does not have concomitant subglottic stenosis or other airway limitation. Other contraindications for endoscopic repair include low birthweight newborns, individuals with craniofacial anomalies, especially micrognathia, and clefts that extend beyond the second tracheal ring (93). Open surgical management through an anterior tracheal split and laryngofissure approach is appropriate for any cleft repair, but it is necessary for a cleft that is too difficult to expose endoscopically or one that is particularly deep. Type IV clefts are extremely rare, and repair is performed on extra-corporeal membrane oxygenation (ECMO) or cardiopulmonary bypass. In these circumstances, ECMO is superior because it can be maintained for 3 to 4 days postoperatively if tracheal swelling precludes intubation. Regardless of the type of cleft, a two-layered closure is desirable (91–93).

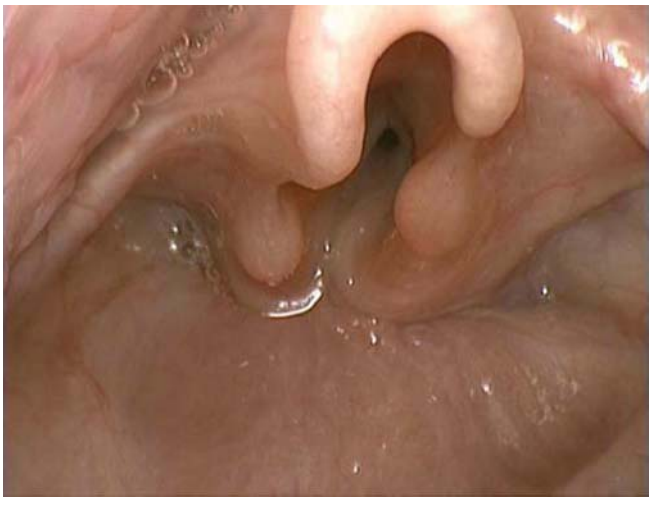

Figure 87.19 Endoscopic photograph of the supraglottic larynx in an infant with a type III laryngeal cleft.

Laryngeal Web

The epithelial lamina of the larynx recanalizes to open into the laryngeal cecum and allows the pharyngoglottic duct to unite with the cecum, thus forming the vestibule and the interarytenoid notch/posterior glottis. Failure of laryngeal recanalization leads to various degrees of laryngeal atresia. Complete atresia comprises the upper anatomical limit of the congenital high-airway obstruction syndrome (CHAOS), but milder versions result in a canalized posterior glottic airway with an anterior glottic web. Miyamoto et al. (95) established an association between velocardiofacial syndrome (22q11 deletion) and anterior glottic webs. Because the subglottic airway bounded by the cricoid cartilage is part of this obliteration/recanalization progression, a laryngeal web often is associated with an elliptical and congenitally stenotic cricoid. The patient presents with inspiratory or biphasic stridor, retractions, a high-pitched or breathy voice, and difficulty feeding due to respiratory limitation. Flexible laryngoscopy may detect a web if a good view of the anterior commissure is achieved. Conventional x-rays alert the physician to concomitant tracheal abnormalities, but for isolated laryngeal webs, imaging adds little. Rigid microlaryngoscopy and bronchoscopy allows for definitive diagnosis. Important considerations at laryngoscopy include the location and thickness of the web and any concomitant airway pathologies, such as congenital subglottic stenosis. When the patient has failed conservative measures, including feeding adjustments and GERD treatment, laryngeal webs merit operative management. A variety of endoscopic and open techniques have been described. Most authors agree that some sort of stent or keel is required after division of the web to keep opposing raw surfaces separated while healing takes place. This usually requires a double staged approach (i.e., the patient has a tracheostomy). However, several reports exist of endoscopic flap rotation with suture fixation and no stenting or endoscopic division with the use of a nonobstructive stent, such as silastic sheeting sutured anteriorly through the thyroid cartilage (96,97). Success is higher with thinner (gossameric) webs regardless of the technique. Thick webs that extend inferiorly into a stenotic cricoid may benefit from concomitant anterior and/or posterior cartilage graft laryngotracheoplasty, as glottic/subglottic webs or stenoses greater than 1 cm in length usually respond poorly to endoscopic incision and dilation alone. It should be noted that CHAOS syndrome in patients with complete laryngeal atresia increasingly is being diagnosed prenatally, and EXIT tracheotomy is lifesaving (22,98).

Tracheobronchial and Esophageal

Relatively common congenital tracheal conditions include tracheomalacia, a tracheal bronchus (pig bronchus) and TEF (99). Congenital tracheal stenosis secondary to complete tracheal rings is rare, but its management principles and techniques can be applied to a variety of tracheal lesions. Pfeiffer syndrome is associated with a cartilaginous "sleeve trachea," which represents a unique type of congenital tracheal stenosis (100). TEF and congenital tracheal stenosis are considered below.

Tracheoesophageal Fistula

Folding and inward movement of the lateral mesodermal ridges between the anterior foregut and the developing airway creates the posterior wall of the trachea that separates it from the esophagus (16). Errors in this mesodermal partitioning may result in a TEF or a laryngeal cleft, or both. In most circumstances, the development of a TEF coincides with failure of caudal development of the esophagus, and 95% of patients with a TEF have esophageal atresia (EA). Up to 60% of patients with TEF/EA have other anomalies (89), and these may be due to a genetic syndrome (such as CHARGE syndrome, Pallister-Hall syndrome, trisomy 18) or a nonsyndromic cause (such as the VACTERL association) (89). The symptoms of TEF/EA depend on the type of anomaly. Five anatomical configurations are commonly described: EA with distal TEF (84%), EA alone (8%), TEF alone (H-type TEF) (4%), EA with proximal and distal TEF (3%), and EA with proximal TEF (1%) (101) (Fig. 87.20). Infants present at birth with copious oral secretions, coughing, gagging, cyanosis, vomiting, and possibly respiratory distress. Only the H-type TEF may remain occult until recurrent episodes of aspiration pneumonia lead to diagnosis. Flexible laryngoscopy to the level of the vocal folds rules out most laryngeal etiologies of aerodigestive tract dysfunction. Today, TEF/EA may be suspected prenatally on ultrasound if a distended esophageal pouch is seen alongside polyhydramnios and the absence of a fluid filled stomach (102). Fetal MRI may be used to confirm the diagnosis (102). Postnatally, classic imaging findings on plain x-ray are a nasogastric tube coiled in the proximal esophageal pouch and a trachea that is compressed and deviated. The absence of a gastric bubble may suggest EA without TEF or EA with a proximal TEF. High-resolution CT scanning with 3-D reconstructions clarifies the anatomy (103). Rigid endoscopy greatly aids in the diagnosis of an H-type fistula, and both the trachea and the esophagus must be examined in the same setting to look for a tracheal mucosal mound, esophageal polyp, and other signs of distal airway inflammation. The initial management of TEF/EA includes placement of a suction catheter to prevent the collection of oral secretions, elevation of the head of the bed, and total parenteral nutrition. Most non-H-type TEFs are repaired along with the EA within the first few days of life. The mobilized atretic esophagus is anastomosed, and the TEF is closed, leaving a long pouch of mucosa on the trachea. Occasionally these tracheal pouches may become symptomatic, collecting secretions or trapping the tip of a tracheostomy tube. Symptomatic tracheal pouches may be endoscopically divided (104). Likewise, endoscopic techniques exist to close recurrent TEFs, possibly obviating the need for a repeat thoracotomy (Fig. 87.21). The tracheomalacia associated with TEF/EA usually resolves with time. If not, tracheomalacia may be managed with tracheotomy with or without pneumatic stenting (positive pressure ventilation). Aortopexy is reserved for specific mid-to-distal focal, pulsatile tracheomalacia that is caused by innominate artery or aortic compression (105).

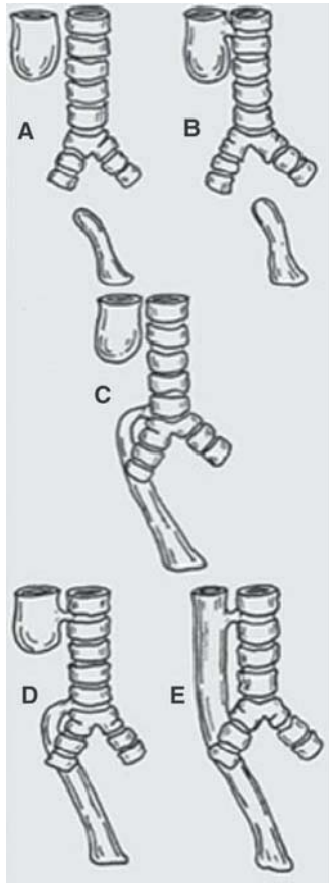

Figure 87.20 Gross classification of EA with and without TEF. The incidence of each type is: (**A**) EA alone (8%); (**B**) EA with proximal TEF (1%); (**C**) EA with distal TEF (84%); (**D**) EA with proximal and distal TEF (3%); (**E**) TEF alone (H-type TEF) (4%).

Congenital Tracheal Stenosis

In the carefully coordinated division of the trachea from the esophagus, contrasting molecular mechanisms are promoting tracheal cartilage development anteriorly and laterally and suppressing it posteriorly. Errors in these molecular mechanisms result in the formation of complete tracheal rings, also known as congenital tracheal stenosis. Infants demonstrate respiratory distress at birth. Breath sounds are characteristically wet in both inspiratory and expiratory phases. Feeding is difficult due to respiratory distress. On occasion, patients with congenital tracheal stenosis have an adequate tracheal airway despite the complete

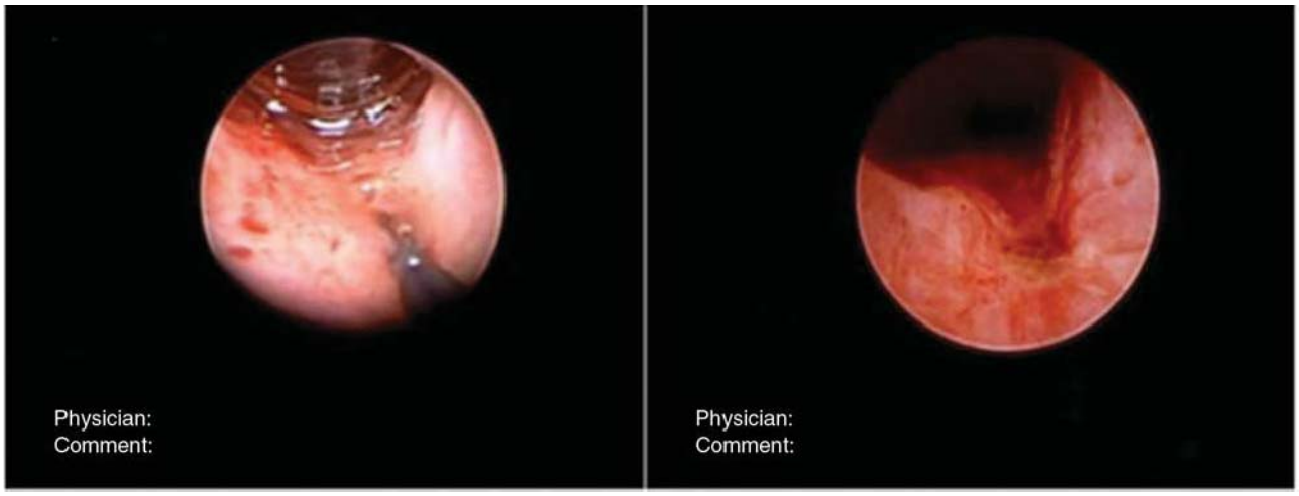

Figure 87.21 Endoscopic photo depicting repair of a recurrent TEF using fulguration, followed by the application of fibrin glue.

tracheal rings, and the ultimate diagnosis remains elusive for months or years (106). Flexible laryngoscopy rules out laryngeal causes of stridor and respiratory distress. If the endoscopist obtains an open glottic view, a stenotic trachea may be visualized. High-resolution scanning with CTA that includes 3-D reconstruction is a useful tool to diagnose the presence of congenital tracheal stenosis (Fig. 87.22), the length of the segment involved (including any bronchial involvement), and presence of concomitant mediastinal vascular anomalies, such as a left pulmonary artery sling. Rigid microlaryngoscopy and bronchoscopy provides a definitive diagnosis. Extreme care must be taken when performing rigid bronchoscopy on a congenitally stenotic trachea. The lumen is often extremely small, and any abrasion from the bronchoscope or telescope can lead to mucosal swelling, tracheal occlusion, and respiratory embarrassment (Fig. 87.23). An incomplete evaluation is preferable to a bad outcome. Goals of endoscopy are to identify the extent and location of the stenosis, the narrowest point in the airway, the diameter at this point and whether any other airway anomalies are present simultaneously, such as a right upper lobe tracheal (pig) bronchus. When the patient's condition demands repair, complete tracheal rings that involve the thoracic trachea require sternotomy. ECMO or cardiopulmonary bypass support gas exchange during repair. Various tracheal repair techniques have been described, including pericardial patch tracheoplasty, long-segment costal cartilage grafting, primary resection and anastomosis, tracheal autograft, and slide tracheoplasty (Fig. 87.24) (107). The latter technique has become the preferred method at experienced centers (48,107,108). Slide tracheoplasty results in a trachea that is half the length and twice the diameter of its

Figure 87.22 3-D coronal CT rendering of a trachea with complete tracheal rings leading to tracheal stenosis.

Figure 87.23 Endoscopic view of the same patient at the level of the glottis. The subglottis was spared, but the first tracheal ring is stenotic.

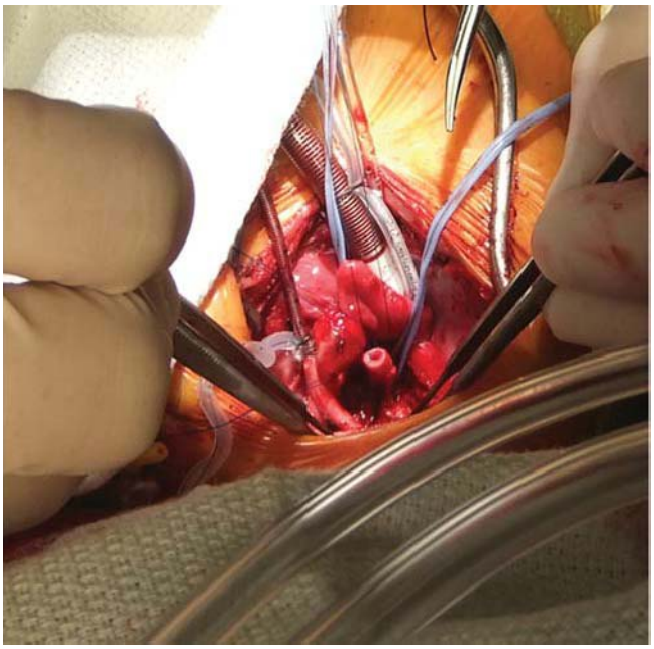

Figure 87.24 Intraoperative photos of the same patient's trachea at transection.

preoperative state (Fig. 87.25) (109,110). The anastomosis is distributed over most of the trachea. As a consequence, focal restenosis is rare, but a "figure of 8" deformity is common. Symptomatic deformities may be managed at surveillance endoscopy with some combination of balloon dilation or laser ablation of infolding tissue.

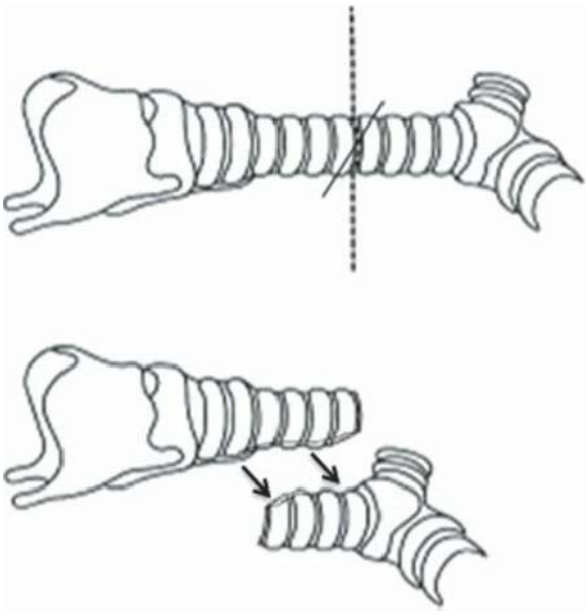

Figure 87.25 Illustration of the slide tracheoplasty technique. The trachea is transected (*dashed line*) at the midpoint of the stenotic segment. A bevel is applied to the upper and lower segments. In this illustration, the posterior wall of the upper segment is incised in the midline through the stenotic portion. The anterior wall of the lower segment is similarly incised, and the two segments are overlapped at anastomosis. Variations of the anterior and posterior tracheal incisions are possible. SUMMARY

Taken in their broadest sense, congenital aerodigestive tract anomalies are relatively common. The aerodigestive tract is charged with feeding, breathing, and voicing, and seemingly isolated anatomical abnormalities produce significant morbidity in the affected individual. Because of this, history and physical examination alone constitute an incomplete workup. The treating physician must be familiar with the appropriate use of flexible endoscopy, imaging, and rigid endoscopy to arrive at the diagnosis as well as to stage dysfunction in other areas of the aerodigestive tract. Undiagnosed comorbidities remain untreated, and untreated comorbidities confound healing after a definitive repair of an aerodigestive tract anomaly. Many centers are increasingly adapting a multidisciplinary model of aerodigestive disease diagnosis and treatment, believing that in the management of these varied and interrelated conditions, many heads are better than one.

HIGHLIGHTS

- Taken as a whole, congenital aerodigestive tract anomalies are relatively common.
- The responsibilities of the aerodigestive tract include feeding, breathing, and voicing, and aerodigestive tract anomalies frequently produce symptoms that involve all three basic functions.
- Flexible and rigid endoscopy and selected radiographic examinations are frequently required to augment a careful history and physical examination in the diagnosis of congenital aerodigestive tract disease.
- The beneficial effects of treatment of an aerodigestive tract anomaly must be weighed against the impact that treatment will have on feeding, breathing, and voicing.
- Modern aerodigestive disease diagnosis and treatment frequently takes place within a multidisciplinary model, combining the expertise of the otolaryngologist with pulmonologists, gastroenterologists, speech pathologists, and other aerodigestive-related practitioners.

88 Neonatal Respiratory Distress

Mark Boston

Respiratory distress occurs in up to 8% of newborn infants and may be manifested by tachypnea, increased work of breathing, nasal flaring, use of accessory muscles of respiration, inspiratory retractions, and cyanosis. Cardiopulmonary problems are the most frequent reasons for neonatal respiratory distress. Sepsis, hypoglycemia, hematologic and metabolic abnormalities, central hypoventilation, and airway obstruction may also cause respiratory distress in the neonate (1).

Congenital upper airway anomalies are rare but can cause significant respiratory distress during the neonatal period (2). Dynamic or fixed obstruction anywhere from the nose and mouth to the tracheobronchial tree may result in respiratory distress. The signs and symptoms of neonatal airway obstruction include noisy breathing (stridor or stertor), feeding difficulties, sternal and intercostal retractions, tachypnea, hypercarbia, hypoxia, cyanosis and, in severe cases, apnea, bradycardia, and cardiac arrest. While the signs and symptoms are often characteristic of the site of obstruction—nasal, oropharyngeal, laryngeal or tracheobronchial—significant overlap exists among the anatomic sites and their presenting symptoms. Therefore, a thorough evaluation of the distressed neonate is essential and includes a detailed history and physical and directed endoscopic, radiographic, and laboratory studies.

ANATOMY AND PHYSIOLOGY

The unique nature of the infant airway must be appreciated in order to appropriately evaluate and manage neonatal respiratory distress. The neonatal larynx is situated high in the neck between the second and fourth cervical vertebrae and forms an obtuse angle with the mandible. The high position of the larynx brings the tip of the epiglottis into contact with the soft palate, making the neonate an obligate nasal breather. The neonatal larynx is softer, collapses easily with higher negative airway pressures, is easily irritated, and is more prone to laryngospasm than is the adult larynx. Laryngeal spasm may result in bronchial constriction, apnea, and bradycardia with life-threatening consequences. Neonates also have small-caliber airways with high resistance, low lung compliance, high chest wall compliance, low oxygen reserve, and high oxygen consumption. As a result, neonates do not tolerate diminished ventilation or apnea for more than a few seconds without developing significant hypoxemia. Therefore, during endoscopic evaluation of the neonatal airway, diligence is required with respect to the appropriate depth of anesthesia, topical anesthesia of the larynx, gastric distention, and blood oxygen saturation monitoring.

EVALUATION

When presented with a neonate in respiratory distress, the physician must first decide if the airway needs to be emergently managed or if he or she can proceed with a detailed history and physical exam (Fig. 88.1). The physician should be able to determine if urgent airway intervention is required within a few seconds by carefully observing the child's level of consciousness, coloring, respiratory effort and listening for airway noise. With a stable or stabilized airway, the assessment may continue in order to determine the specific etiology of the airway obstruction. In all cases of neonatal airway distress, the history must include a detailed accounting of the pre- and perinatal histories, family history, onset and timing of airway noise, associated feeding difficulties, and the presence or absence of other associated signs and symptoms. Examination may follow the history or proceed simultaneously with active airway management in the severely distressed neonate.

The history, time of onset, and identification of initiating factors are helpful in the search for the cause of stridor in the neonate. The effects of positioning, feeding, or crying offer further diagnostic clues. A history of prematurity, difficult

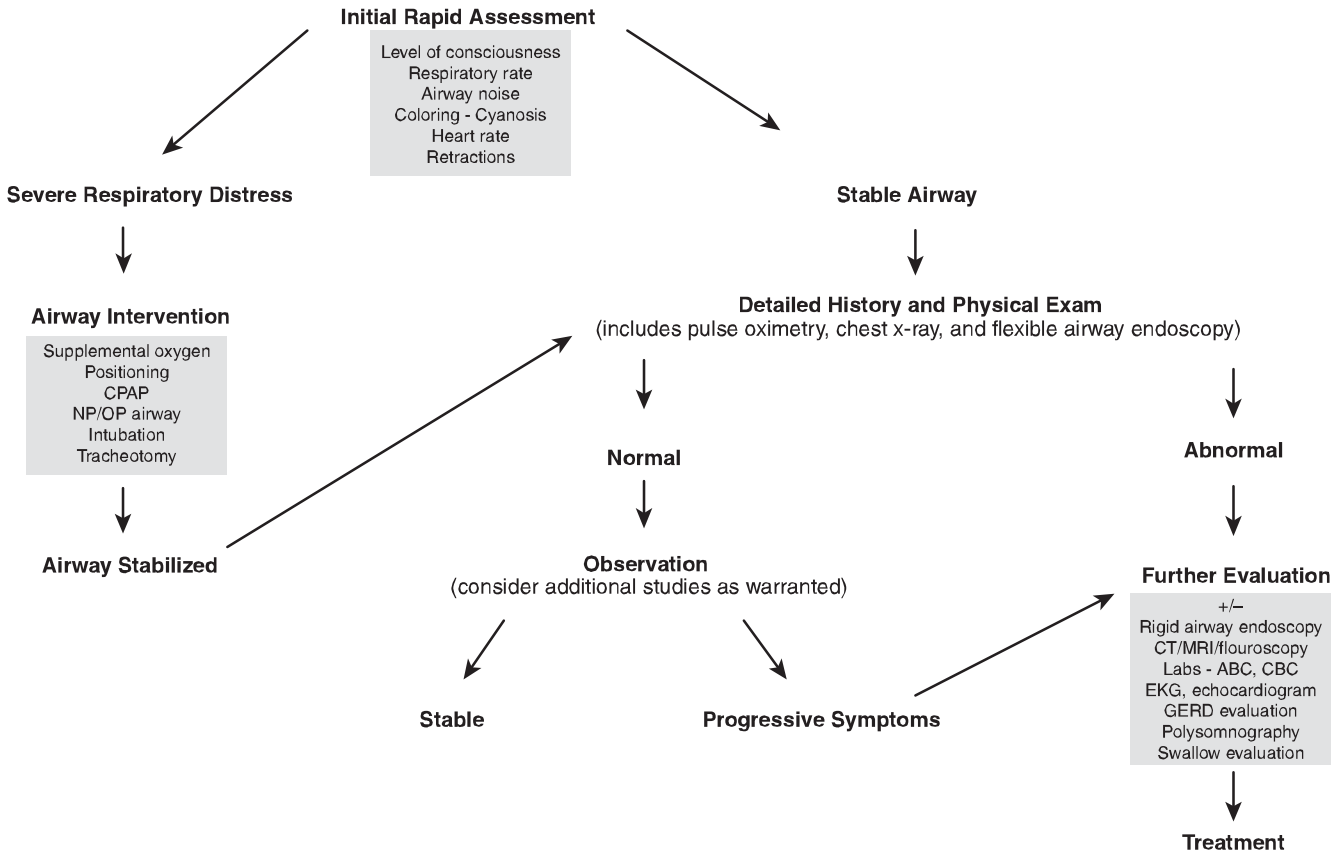

Figure 88.1 Algorithm for the evaluation and treatment of neonatal airway obstruction.

labor or delivery, or intubation may be contributory. The quality of stridor and its relationship to the respiratory cycle offer valuable diagnostic clues as does the character of the newborn's cry and the presence of dysphagia or a cough. The neck and lungs should be auscultated and, after completing the history and general physical examination, the airway should be examined endoscopically.

Flexible endoscopy using a pediatric flexible laryngoscope should be performed in all neonates with suspected airway obstruction. Care must taken, however, to ensure that the patient is stable for the exam and that the procedure will not exacerbate the airway problem. The pediatric flexible laryngoscope is used to assess the nose, nasopharynx, oropharynx, and larynx to the glottis and the upper hypopharynx. However, the pyriform sinuses, posterior cricoid region, and subglottis cannot be consistently examined with this technique. Whenever possible, the study should be performed with a camera attachment and recorded for documentation and review. Application of a topical nasal decongestant may be helpful, but the routine use of topical anesthesia is not necessary (3).

Not all neonates with suspected congenital airway obstruction need undergo rigid endoscopic examination under anesthesia if the diagnosis can be obtained confidently by a combination of flexible endoscopy and/or radiographic studies; however, if patients show a progression of symptoms marked by increasing respiratory distress or failure to thrive, microlaryngoscopy, bronchoscopy, and esophagoscopy are indicated for both diagnostic and therapeutic reasons.

Continuous pulse oximetry monitoring and a chest radiograph are standard for all neonates in respiratory distress (1). Additional studies are directed based on the history, general physical examination, endoscopic examination, and radiographic findings. In patients with suspected tracheomalacia, videofluoroscopy helps delineate the full extent of luminal collapse and diaphragmatic excursion (4). A contrast esophagogram can be useful in the diagnosis of tracheoesophageal fistulae, esophageal stenosis, and vascular anomalies or rings that cause extrinsic compression. Detailed information regarding airway stenosis, mass lesions, or thoracic vascular abnormalities may be provided by computed tomography (CT) or magnetic resonance imaging (MRI) (5). An echocardiogram and electrocardiogram are useful to assess for cardiac abnormalities and possible cardiac strain. An evaluation for gastroesophageal reflux disease (GERD) will be appropriate in selected patients and may include a pH probe study, esophagoscopy with biopsies, barium swallow, or esophageal scintiscan. When aspiration is suspected, a functional endoscopic evaluation of swallowing (FEES) may be useful.

After the diagnosis has been obtained, a treatment plan is instituted. In the patient with progressive respiratory distress but no identified airway obstruction, the physician should consider pulmonary, cardiac, central nervous, gastrointestinal, iatrogenic, or metabolic–nutritional causes of respiratory failure. If there is an upper airway abnormality, bypassing the obstruction should relieve the symptoms of respiratory distress. With coexisting pulmonary pathology, however, the patient may remain symptomatic with tachypnea, hypoxemia, and hypercarbia, and require ventilatory assistance. When upper airway pathology has been eliminated as a cause of the patient's respiratory distress, the neonatologist should assume primary management of the patient.

NOSE

Because infants are initially obligate nasal breathers, nasal obstruction frequently causes severe respiratory distress in neonates. Nasal obstruction typically results in stertor, a sonorous or snorting type of respiration, with nasal flaring. With complete nasal airway obstruction (e.g., bilateral choanal atresia) cyanotic episodes are frequent and may be alleviated during crying, a phenomenon known as cyclical cyanosis. Chest retractions are common and feeding is difficult because patients must breathe and feed through their mouths at the same time. Severe respiratory distress due to nasal obstruction should be managed with an oral airway or intubation prior to completing the history and examination.

Examination begins with an external assessment of the nose and surrounding facial structures. Small pits or dimples along the midline of the nose suggest a nasal dermoid (6). These may be found from the nasal dorsum to the columella. Similarly, a midline nasal mass may represent a cephalocele, glioma, teratoma, or extension of an intracranial vascular anomaly. Craniofacial anomalies, including Treacher Collins, Crouzon, and Apert syndromes, may present with nasal obstruction, and recognition of these anomalies should direct the examination to the nose and nasopharynx (7). Large intranasal hemangiomas or vascular malformations may also cause respiratory distress and may cause distortion of the external nose.

After the external assessment, a thorough intranasal examination should be undertaken. The most common cause of neonatal nasal airway obstruction is neonatal rhinitis. The patient with neonatal rhinitis typically presents with stertor and feeding difficulties. Examination reveals diffuse nasal mucosal edema and turbinate hypertrophy with a normal pyriform aperture and patent choanae. Treatment includes the use of nasal saline drops and or 0.1% dexamethasone ophthalmic drops into both nostrils for several days. GERD may also contribute to neonatal rhinitis and should be treated if suspected based on the history and physical examination.

Anterior nasal stenosis is uncommon, but obstruction at the level of the pyriform aperture secondary to medial overgrowth of the maxilla may cause distress. Airway distress may be especially prominent if there is associated turbinate hypertrophy. Examination of the intranasal structures with a flexible nasopharyngoscope or rigid telescope can identify the cause of obstruction. Inability to pass an endoscope through the anterior nose due to narrowing of the nasal fossa should alert the clinician to the possibility of pyriform aperture stenosis. Although rare, pyriform aperture stenosis can be associated with a single upper central incisor or other craniofacial dysmorphology (8,9). The inferior meatus should be examined carefully for nasolacrimal duct cysts (Fig. 88.2). Passing the nasopharyngoscope more posteriorly allows examination of the posterior choanae and nasopharynx. If choanal atresia is suspected because of the inability to pass either a nasopharyngoscope or a small feeding tube more than 5.5 cm from the alar rim, CT evaluation is appropriate (Fig. 88.3) (10,11). Children with either pyriform aperture stenosis or choanal atresia should be assessed by a geneticist because of a high incidence of concomitant craniofacial and developmental anomalies (e.g., CHARGE syndrome) (10). Adenoid hypertrophy or a nasopharyngeal tumor also may be identified as a cause of nasal airway obstruction.

Radiographic assessment of neonates with nasal obstruction is often necessary, and CT is the preferred study for most cases of neonatal nasal obstruction. In some conditions, however, including midline nasal masses with potential intracranial connections, MRI may also be indicated (6). Consultation with a pediatric neuroradiologist is recommended to optimize the radiographic evaluation of these patients.

Figure 88.2 A nasolacrimal duct cyst may be identified under the inferior turbinate and may cause nasal obstruction. Such children often present with concomitant dacryocystitis.

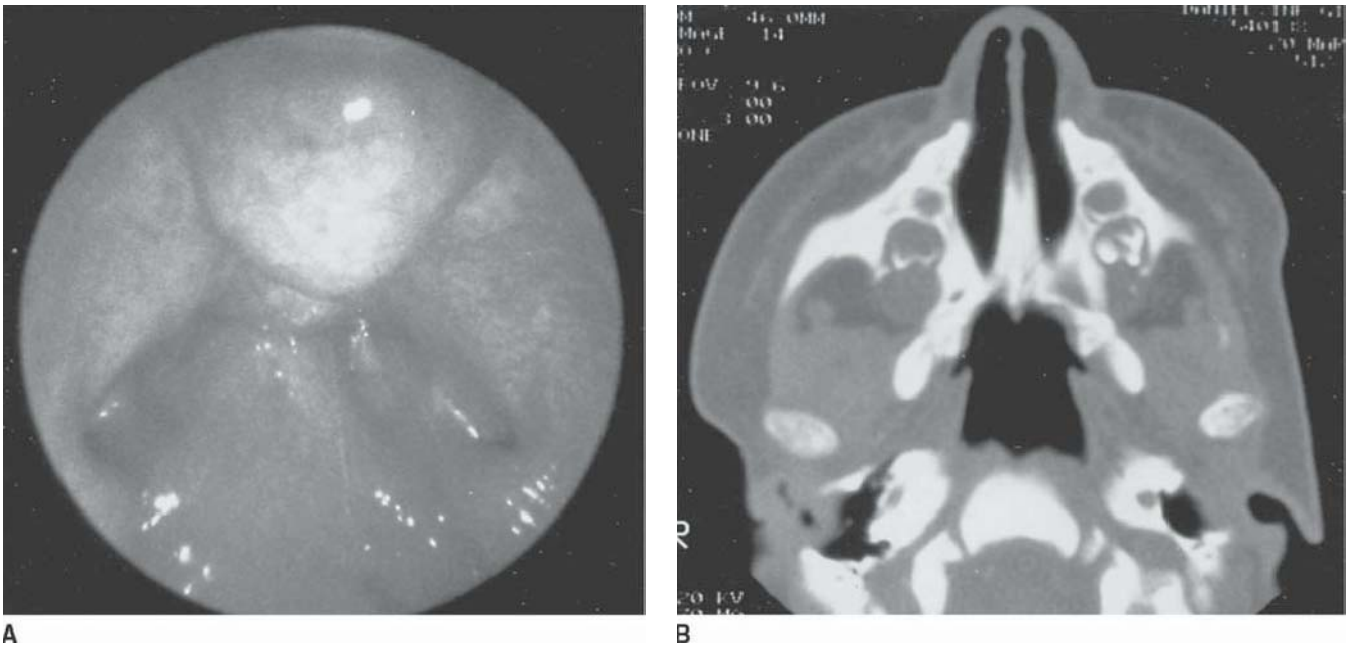

Figure 88.3 Choanal atresia may be identified endoscopically as seen in this view with a 120-degree telescope (**A**) and confirmed by CT scan (**B**).

Regardless of the cause of obstruction, establishing a secure airway is paramount. In many circumstances, this must be done prior to any investigative procedures. If the child has no underlying lung disease or laryngotracheal abnormalities, placement of an oral airway may be sufficient. An alternative to the conventional oral airway may be a feeding nipple cut at the end. Either of these should be secured by taping or with tracheotomy ties placed around the head. Oxygen saturation monitoring can determine the efficacy of this maneuver and, if the child does not maintain adequate oxygen saturation levels, supplemental oxygen may be required. Alternatively, orotracheal intubation with possible ventilatory support may be required. In any child with airway obstruction, failure to maintain adequate ventilation with an endotracheal tube in place may signify intrinsic pulmonary disease, and the active assistance of a neonatologist should be obtained (1).

ORAL CAVITY/OROPHARYNX/ HYPOPHARYNX

Examination of the mouth, oropharynx, and hypopharynx follows the nasal exam. Patients with obstruction in this area usually present with coarse inspiratory stertor that increases during sleep. The cry is usually normal, but may be muffled. Suprasternal and sternal retractions are common and may increase to total chest retractions with severe obstruction. Feeding may be difficult or impossible because of an anatomic obstruction. The airway noise is frequently worse with supine positioning, feeding, and agitation. If immediate intervention is needed, placement of an oral airway, nasopharyngeal airway, or endotracheal tube should be considered.

The presence of macroglossia, glossoptosis, or tumors should be ascertained during examination of the oral cavity and oropharynx. Congenital tumors may include teratomas (epignathus tumors), oral hairy polyps, or malignancies. A flexible endoscopic examination performed through the mouth or nose may demonstrate a mass in the vallecula, including a lingual thyroid, dermoid, or vallecular cyst. Hemangiomas, lymphatic malformations, or other vascular malformations may be identified. Children with craniofacial disorders and Down syndrome are at increased risk for oropharyngeal airway obstruction (7). The findings of micrognathia and glossoptosis in a neonate with airway obstruction are pathognomonic for Robin sequence (12).

If no obvious anatomic abnormality can be identified from the examination, but the child demonstrates evidence of airway obstruction at the oropharyngeal or hypopharyngeal level, a videofluoroscopic examination to observe dynamic changes of the airway may allow a diagnosis to be rendered. Glossoptosis, pharyngeal wall collapse, or laryngomalacia, a supraglottic cause of airway obstruction, may be identified by fluoroscopy. Cine MRI and multidetector CT evaluations are emerging as valuable tools in the assessment of dynamic airway collapse and can quantify the degree of obstruction at various sites in the airway (13,14). These studies, however, require cooperative or intubated patients and are not suitable for most neonates in respiratory distress. The routine use of pulse oximetry is important in the ongoing assessment of airway obstruction at any level of the airway.

Severe respiratory distress in patients with oropharyngeal or hypopharyngeal obstruction mandates immediate airway support. In some cases, the use of a nasopharyngeal or oropharyngeal airway may be all that is required. When

pharyngeal and/or hypopharyngeal collapse is present, the use of nasal continuous positive airway pressure may also relieve symptoms. In children with glossoptosis and retrognathia (e.g., Robin sequence), prone positioning may be beneficial. Pulse oximetry monitoring may be required during the first several months for an infant with Robin sequence because some of these children tend to develop progressive airway obstruction. Even if the child is relatively asymptomatic, intubation may be problematic because of the micrognathia and glossoptosis. Rigid bronchoscopy may be necessary for airway control and, in some circumstances, a tracheotomy with spontaneous mask ventilation may be needed (12).

Most infants with Robin sequence may be observed with monitoring and positioning to relieve their airway obstruction. Feeding is also often compromised and must be addressed through the use of special nipples or, in some cases, nasogastric or gastric tube feeding. A tracheotomy provides the most definitive airway for infants with Robin sequence and severe airway distress, although not without potential morbidity. If the child with Robin sequence has a cleft palate, the tracheotomy is not removed until the cleft palate is repaired. If there is no cleft palate, then the tracheotomy can be removed after the airway obstruction resolves, generally in a few months. Glossopexy (tongue–lip adhesion) or the use of a nasopharyngeal airway has been advocated as an alternative to tracheotomy in children with Robin sequence and airway obstruction that does not respond to positioning (12). Distraction osteogenesis of the mandible is a promising alternative to tracheotomy in selected infants with micrognathia and tongue base obstruction (15,16). Determining which children will benefit from distraction osteogenesis and which will require a tracheotomy, however, remains a clinical challenge.

LARYNX

The larynx is the most common site of stridor in infants. Children with supraglottic or glottic laryngeal abnormalities often present with a combination of problems involving respiration, phonation, and swallowing. In severe cases, suprasternal and intercostal retractions may be seen. Feeding is typically impaired and aspiration may occur if there is a mass lesion, cleft, or neurologic disorder. Infants with supraglottic laryngeal obstruction may present with a muffled cry and they frequently produce snorting respirations during sleep and coarse inspiratory stridor at rest (17).

Laryngomalacia is the most common laryngeal cause of respiratory distress and the most frequent cause of inspiratory stridor in infants. Laryngomalacia is thought to result from alteration of the laryngeal adductor reflex and may be exacerbated by GERD and neurologic disorders (18). Laryngomalacia is initially suspected in the neonate with inspiratory stridor that is worsened by supine positioning, feeding, and agitation. The stridor and airway distress of laryngomalacia are often not present at birth, but tend to worsen over the first few weeks of life. The presence and

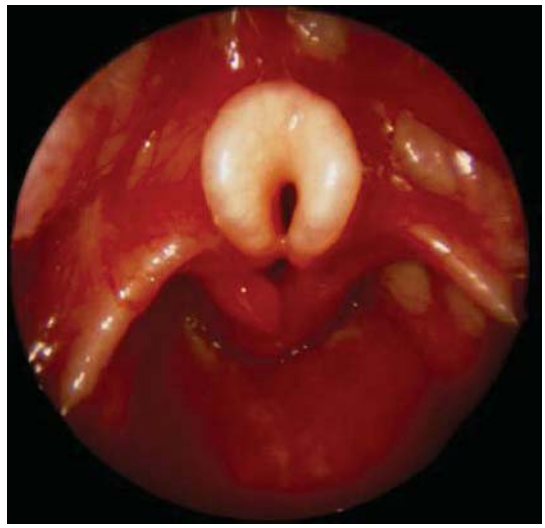

Figure 88.4 Laryngomalacia is demonstrated best by flexible laryngoscopy, but it may be demonstrated satisfactorily with rigid endoscopy.

severity of laryngomalacia is assessed with awake flexible laryngoscopy by observing the prolapse of the arytenoids and/or epiglottis into the laryngeal airway during inspiration (Fig. 88.4). The finding of an omega-shaped epiglottis by itself is not diagnostic of laryngomalacia. In rapidly breathing and crying infants, the examiner must take care in determining during which phase of respiration the supraglottic structures are observed to collapse or compress into the airway. While awake flexible laryngoscopy is the primary study needed to make the diagnosis of laryngomalacia, many children with laryngomalacia, especially those with severe airway distress requiring surgical intervention, have additional airway lesions, and consideration should be given to rigid endoscopic evaluation of these children (19). A FEES study is valuable for assessing the risk of aspiration, and videofluoroscopy may be used to look for concomitant tracheomalacia in children with laryngomalacia (4).

Flexible endoscopic evaluation of the larynx may also reveal the presence of supraglottic or glottic tumors, cysts, or webs. A CT or MRI scan is almost always needed for a thorough assessment of a mass lesion of the supraglottic larynx. In some patients, a diagnosis cannot be determined via these investigative means and then microlaryngoscopy, bronchoscopy, and esophagoscopy should be performed. Depending on the pathologic condition encountered, direct surgical intervention, including supraglottoplasty, or cyst aspiration, or marsupialization, may be appropriate. In other circumstances, endotracheal intubation or tracheotomy is necessary before performing definitive surgery at a later date.

Neonates with glottic airway obstruction may present with a combination of inspiratory or biphasic stridor, an abnormal cry, feeding difficulties, or aspiration. With severe obstruction, inspiratory and expiratory stridor, chest retractions, and nasal flaring are common. A flexible

Figure 88.5 In this autopsy specimen, the larynx has been sectioned in a superior to inferior manner (**right** to **left**) demonstrating laryngeal atresia (**right**) and a laryngotracheoesophageal cleft (**left**).

laryngoscopic examination is essential in the evaluation of the glottis because vocal fold paralysis is a dynamic process that cannot be readily determined when a patient is anesthetized. Because it may be difficult to assess vocal fold function in a crying neonate, it is helpful to record the flexible laryngoscopy study for later review. In neonates with a history of intubation, suspension laryngoscopy is necessary to assess for cricoarytenoid joint dislocation or fixation. Patients with vocal fold paralysis should also have MRI or CT scans performed to look for potential central nervous system lesions or cardiovascular abnormalities. Additionally, a video swallow study or FEES can be invaluable in helping to determine the presence and severity of aspiration in children with laryngeal abnormalities.

Neonates with unilateral vocal fold paralysis typically present with an abnormal cry, cough, or aspiration. Airway distress is more common with bilateral vocal fold paralysis, but can also occur in neonates with unilateral vocal fold paralysis. Children with bilateral vocal fold paralysis usually have a normal cry and biphasic stridor. The search for the cause of vocal fold paralysis includes CT and/or MRI scans of the head and chest to evaluate for neurologic (e.g., Arnold-Chiari malformation, hydrocephalus) or cardiovascular etiologies. Surgery to repair a patent ductus arteriosus or other cardiac abnormality may result in vocal fold paralysis. Other cases of unilateral vocal fold paralysis may be due to birth trauma or may be idiopathic (viral neuritis or delayed neural maturation) and often these patients regain normal vocal fold function over several weeks or months. While spontaneous recovery of bilateral vocal fold paralysis is possible, these children tend to have significant airway distress and many require a tracheotomy. Some children with bilateral vocal fold paralysis may avoid a tracheotomy, but they must have understanding and cooperative caregivers and be followed closely for years. Many of these children may require surgical procedures as they grow and their increased size and activity levels place greater demands on their airways. Because of the possibility of spontaneous recovery of vocal fold function, conservative and reversible laryngeal procedures are preferred during the first year of life (20).

Although other laryngeal abnormalities may be diagnosed with a flexible examination, including webs, atresia, neoplastic disorders, stenosis, and clefts, a rigid examination allows a more detailed and complete assessment to be made. Laryngeal atresia is rare and incompatible with life (Fig. 88.5). If it is identified, an emergent tracheotomy may be necessary; however, some of these patients may have an associated laryngotracheoesophageal cleft or a tracheoesophageal fistula that allows ventilation and oxygenation for a period of time. Patients with partial glottic obstruction can often be initially managed with endotracheal intubation.

Another potential cause of airway obstruction at the glottic level is laryngospasm. This may occur secondary to GERD and should be considered when the cause of obstruction is recurrent or obscure. In addition, GERD has been implicated as a causative or contributing factor in patients with apnea, apparent life-threatening episodes, chronic cough, laryngomalacia, recurrent croup, and subglottic stenosis (21). Gastroesophageal reflux is a common physiologic finding in most neonates and the relationship between neonatal extraesophageal reflux and airway obstruction is not certain (22). Consultation with a pediatric gastroenterologist may be appropriate before assessing the patient with a pH probe study, barium esophagogram, gastric scintiscan, or esophagoscopy with biopsy. A recent systematic review stratified laryngeal endoscopy findings and the presence of GERD and found the strongest correlation with vocal fold edema and posterior glottic edema and erythema (23). These findings, however, are not specific in neonates. Treatment for GERD in infants may include medications or surgery, depending on the severity of the problem.

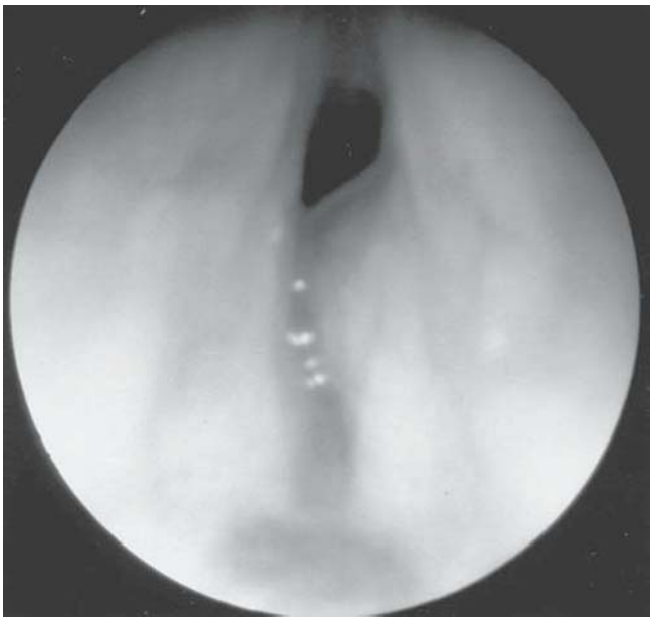

Figure 88.6 A subglottic hemangioma is characteristically located in the posterior and lateral portion of the larynx.

Neonates with subglottic airway obstruction may have a hoarse cry, but often the cry is normal. Similar to patients with glottic obstruction, infants with subglottic obstruction present with inspiratory stridor that can become biphasic as the obstruction increases. Xiphoid retractions are seen early in the course of subglottic obstruction and, as the obstruction increases, retractions may be seen in the intercostal, suprasternal, and supraclavicular regions. Infants with subglottic airway obstruction usually feed normally except when the airway obstruction is severe. Alar flaring may be seen and a barking cough is not uncommon with subglottic obstruction.

Flexible endoscopic examination of the airway alone is not sufficient for evaluating subglottic obstruction. The optics of the flexible laryngoscope do not allow for optimal examination of the subglottic airway and the common anatomic problems seen in this region, including stenosis, cysts, and hemangiomas, may be missed (Fig. 88.6). If the child's symptoms cannot be explained fully on the basis of the flexible endoscopic evaluation and radiographs, microlaryngoscopy, bronchoscopy, and esophagoscopy are necessary. When subglottic obstruction causes severe airway distress, intervention with an endotracheal tube or a tracheotomy may be necessary before definitive surgical repair is undertaken.

Congenital subglottic stenosis is uncommon but must be considered in the neonate with inspiratory or biphasic stridor. An elliptical-shaped cricoid ring may be seen on rigid endoscopy. Symptomatic neonatal subglottic stenosis may be surgically treated by tracheotomy, endoscopic dilation, laser procedures, anterior cricoid split, or laryngotracheoplasty (24,25). Subglottic webs and cysts may be treated by endoscopic division or marsupialization using cold steel, laser, or diathermy.

Although not typically symptomatic at birth, most subglottic hemangiomas become clinically apparent during the neonatal period. Infants with persistent "croup" symptoms should be suspected of having a subglottic hemangioma. Physical examination will reveal a cutaneous hemangioma of the head or neck in approximately 50% of infants with a subglottic hemangioma. Diagnosis is made by endoscopy, although MRI may be helpful to delineate the extent of the hemangioma. Recently, propranolol has been advocated as a primary treatment for subglottic hemangiomas and has shown promising results (26). Steroids, laser ablation, open surgical excision, and tracheotomy are other treatment options (27).

TRACHEA/BRONCHI

Patients with tracheobronchial obstruction usually present with a normal cry, expiratory stridor, and there may be a component of wheezing. With severe obstruction, the stridor may become biphasic. Nasal flaring is common and these patients may have a brassy cough. Retractions are uncommon unless there is severe obstruction. Feeding may be impaired with severe airway obstruction or with extrinsic compression of the esophagus.

The evaluation of patients with suspected tracheobronchial lesions includes anteroposterior and lateral chest radiographs, airway fluoroscopy, and a barium esophagogram. Many clinicians prefer to perform a rigid endoscopic examination before obtaining a contrast esophagogram. If fistulae are observed along the posterior tracheal wall, an attempt at catheterization can be made to demonstrate continuity with the esophagus. Airway fluoroscopy can aid in the differentiation of tracheomalacia and tracheal stenosis. Depending on the severity of the obstruction, immediate intubation may be necessary. After the airway is stabilized, the diagnosis of compressive lesions of the trachea and esophagus can be made with either MRI or CT angiography. Vascular rings, innominate artery compression of the trachea, and mediastinal cysts and neoplasms may all be identified by MRI and CT.

Intrinsic abnormalities of the tracheobronchial tree include primary tracheomalacia, complete tracheal rings, tracheoesophageal fistulae, and tracheobronchial tumors and cysts. Complete tracheal rings may involve a short segment or the entire trachea. Initial airway management may include intubation to the proximal end of the stenosis or the use of extracorporeal membrane oxygenation. Tracheotomy should be avoided in patients with complete tracheal rings because it may further compromise the airway. Slide tracheoplasty has emerged as the definitive treatment of choice for complete tracheal rings (28).

Primary tracheomalacia is thought to be due to a structural weakness of the tracheal cartilage that results in tracheal airway collapse during expiration. This condition generally improves over the first 2 years of life although

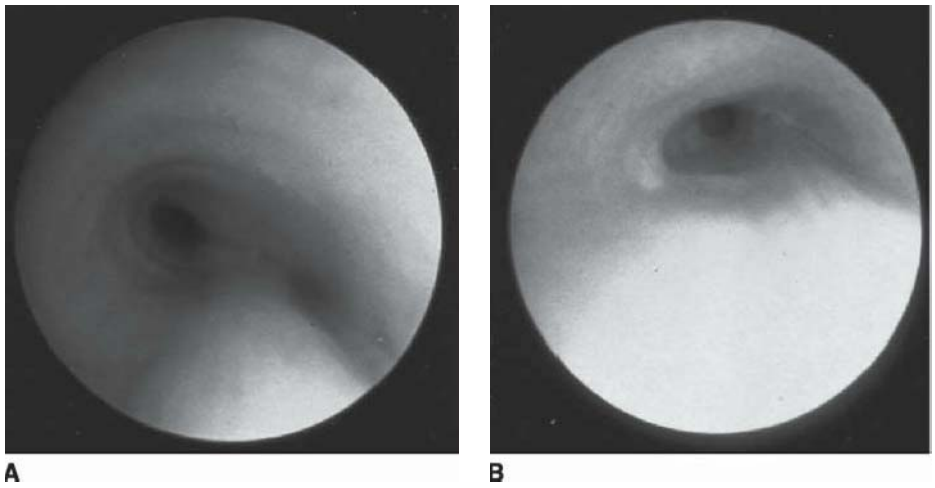

Figure 88.7 Vascular compression of the trachea as seen by tracheoscopy. These views demonstrate examples of innominate artery compression of the trachea (**A**) and a right aortic arch (**B**).

some children require a tracheotomy to bypass or stent open the collapsing area. Secondary tracheomalacia is more common and is the result of extrinsic tracheal compression, most often from vascular abnormalities (27). Neonates with significant tracheobronchomalacia may present with dying spells.

Extrinsic compressive abnormalities of the tracheobronchial tree are more common than intrinsic abnormalities and most cases of neonatal tracheobronchial obstruction are caused by thoracic vascular anomalies. Vascular anomalies causing tracheobronchial compression include an anomalous innominate artery, aberrant aortic arch, and a pulmonary artery sling (29). Endoscopic examination demonstrates the compressive nature of the anomaly and dictates further investigative and therapeutic maneuvers (Fig. 88.7). Esophagoscopy may confirm the compressive nature of the lesion or offer evidence of an alternative pathology, such as esophageal atresia.

PRENATAL FETAL ASSESSMENT

Advances in fetal assessment have allowed physicians to identify potentially life-threatening abnormalities of the developing fetus prior to birth. Fetal MRI provides detailed information regarding the fetal neck, larynx, and trachea, and this information can be used to stratify risk and plan for appropriate interventions. Teratomas and lymphatic malformations are the most common fetal cervical tumors; however, teratomas are much more likely to cause significant airway compromise in the developing fetus and these patients are the ones most likely to benefit from a multidisciplinary fetal center (Fig. 88.8) (30).

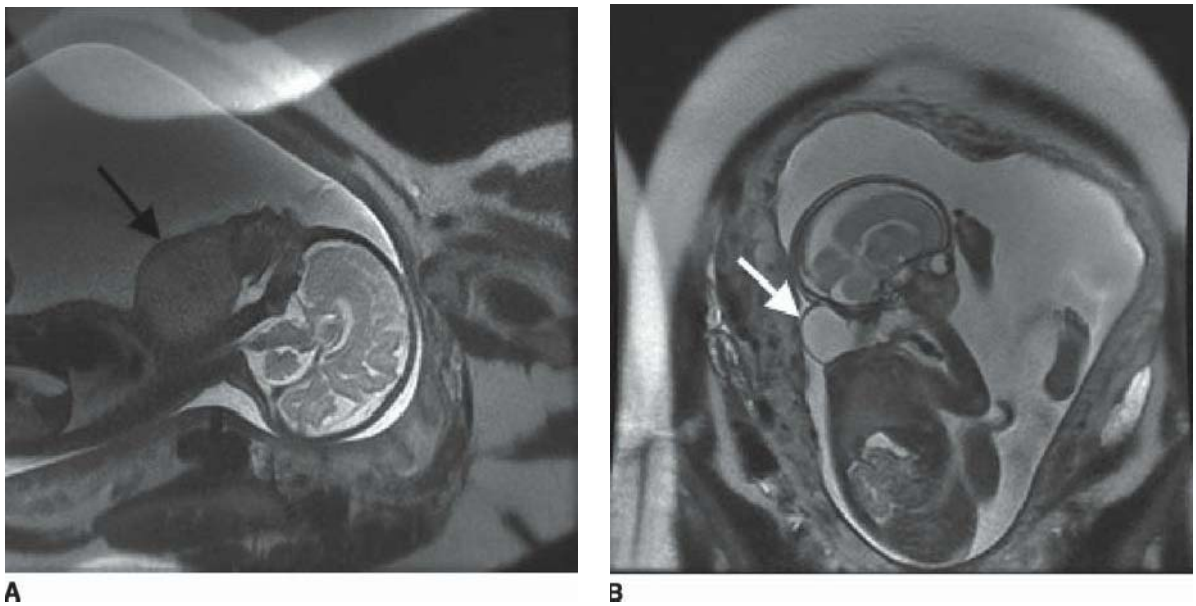

Figure 88.8 Fetal MRI provides detailed imaging of congenital cervical masses that may cause airway obstruction. These sagittal images demonstrate a cervical teratoma (*black arrow*) in (**A**) and a lymphatic malformation (*white arrow*) in (**B**). These studies allow for maternal counseling and planning for airway control at delivery.

The ex utero intrapartum treatment (EXIT) involves a planned Cesarean delivery under deep general anesthesia with delivery of only the fetal head and one or both shoulders. With the fetus maintained on placental circulation the surgeon has several minutes in which to secure the airway. The method of airway management during an EXIT procedure depends on the location of the mass and includes intubation, tracheotomy, distal tracheotomy with retrograde intubation, or mass excision. Proper planning by a skilled, multidisciplinary EXIT team can result in life-saving outcomes for newborns with large, obstructive tumors of the head and neck (31).

HIGHLIGHTS

- Rapid recognition of the severity of neonatal respiratory distress is essential to determining if airway intervention is needed before a complete history and physical exam are performed.
- Because neonates are obligate nasal breathers, nasal obstruction may precipitate life-threatening hypoventilation.
- Beyond the history and general physical examination, flexible airway endoscopy, a chest x-ray, and pulse oximetry are critical in the evaluation of neonatal airway obstruction.
- Airway obstruction at the oropharynx typically causes stertor and feeding problems.
- Most patients with Robin sequence can be managed with close observation, positioning, and monitoring.
- Laryngomalacia is often not clinically apparent at birth but progressively worsens over the first few weeks of life.
- All children with upper airway obstruction must be evaluated for their ability to feed and tube feedings instituted if they cannot maintain adequate caloric intake by mouth.
- Patients with glottic or subglottic airway obstruction typically present with inspiratory or biphasic stridor and an abnormal cry.
- Tracheomalacia is typically the result of compression by thoracic vascular abnormalities and MRI or CT is needed to properly define the problem.
- Differentiating between upper airway obstruction and primary pulmonary abnormalities is critical. Although the former may respond to intubation or tracheotomy, management of the later may require mechanical ventilation.
- The prenatally diagnosed fetus with a cervical mass suspicious for a teratoma should be considered for an EXIT procedure.

89 Stridor, Aspiration, and Cough

Joseph E. Dohar *Samantha Anne*

INTRODUCTION

Love and a Cough Cannot be Hid

No truer words than these by George Hebert. Few signs and symptoms are perceived as being as distressing to parents as cough, aspiration, and stridor. At a glance, one may consider "stridor," "aspiration," and "cough" as each constituting chapters unto themselves. What unifies these three entities is their anatomic and functional interrelatedness that often results in the concomitant concurrence of all three. Although this chapter discusses each independently, the clinical reality is that any disruption of the complex structure and function of the upper aerodigestive tract often adversely alters the delicate coordination between swallowing and respiration. Hence, it is not uncommon for any combination of these three signs and symptoms to coexist. Even in clinical presentations where only one of these signs dominates, the astute clinician will always search for the other two. This is especially true for aspiration that is not uncommonly "silent" in children. Not only is such an assessment diagnostically imperative but also therapeutically significant as management is vastly altered by the relative proportionate degree to which each of these is playing a role. It is no wonder then that pediatric aerodigestive centers of excellence have emerged in tertiary children's hospitals as representative of the "gold standard" of such care. Such environments are predicated upon the dynamic overlap between stridor, aspiration, and cough. They integrate an interdisciplinary and systematic means by which to assess all three by combining traditional and fundamental tools with more recently developed diagnostic evaluations such as functional endoscopic evaluations of swallowing (i.e., FEES) and breathing.

STRIDOR

Stridor is an abnormal sound due to turbulent airflow through a partially obstructed airway. The level of obstruction can often be clinically localized to the supraglottis, the glottis, or the subglottis and trachea based on the characteristics of the stridor. Specifically, the type of stridor, whether inspiratory, expiratory, or biphasic, helps to localize the site of obstruction. Supraglottic obstruction generally presents with inspiratory stridor while intrathoracic obstruction presents with expiratory stridor. Fixed anatomic obstructive lesions tend to cause biphasic stridor. Finally, the quality of stridor may also provide clues to location and etiology. For example, high-pitched inspiratory stridor is nearly always seen in neonates with laryngomalacia.

Evaluation

The evaluation of a child with stridor begins with a thorough history and physical examination from which most often a differential diagnosis is derived. The most important step in evaluating a child with stridor is determining acuity of the respiratory distress. For an actively stridorous child with severe retractions and impending obstruction, urgent airway stabilization is necessary. Once stabilized, a full evaluation can follow.

History and Physical Exam

The perinatal history specifically determining whether or not endotracheal intubation or airway intervention was required is paramount. The onset, triggers, progression, and presence of exacerbating and/or alleviating factors must also be ascertained. Associated symptoms including presence of aspiration or difficulty with feedings, hoarseness, and signs of reflux must be identified. Positional

changes that worsen or lessen stridor should be noted as well as recurrent or persistent croup episodes. Noting cyanotic spells or apneas helps to quantify the severity of the obstruction. Lastly, comorbidities such as neurologic abnormalities and past surgeries such as those to correct congenital cardiac anomalies must be recorded.

The physical examination begins with an overall impression of the child without invoking excitement. Vital signs must be reviewed for the presence of fever suggestive of an acute infectious etiology, tachypnea, oxygen desaturations, and tachycardia. Dysmorphic features may suggest a syndrome. Observe the child for audible stridor at rest, signs of increased respiratory work including subcostal, intercostal, and suprasternal retractions. Some clinicians may confuse stertor with stridor, and this distinction must be ascertained as early as possible since the subsequent evaluation differs for each. Voice and/or cry quality should be perceptually assessed. Dysphagia may be immediately evident as drooling. A thorough head and neck examination must follow with careful attention to palpation and visualization of any masses within oropharynx and neck. Auscultation of the upper airway and chest qualifies the type of stridor and identifies its phase of occurrence as inspiratory, expiratory, or biphasic.

Radiology

Useful imaging may include chest and neck radiographs. Chest radiographs, in anterior–posterior, lateral upright, and lateral decubitus projections can aid in the diagnosis of several causes of stridor. Inspiratory/expiratory films can reveal foreign bodies in the central airway as well as in the bronchi. Biphasic radiographs may also reveal hyperinflation from obstructing lesions or lower airway disease such as infiltrates or pneumonias. Lateral neck films can reveal key findings such as the "thumbprint" sign of inflamed epiglottis in epiglottitis or thickened retropharyngeal soft tissue in phlegmon- and/or abscess-related airway obstruction.

Computed tomography (CT) and magnetic resonance imaging (MRI) can be used for airway evaluation but do not replace a thorough endoscopic evaluation of airway stenosis or malacia. CT with contrast identifies extrinsic masses or vascular lesions that compress the airway. Both CT and MRI can be used to evaluate vascular malformations in general.

Endoscopy

Following a careful selection of radiologic imaging and after a thorough examination of the child, endoscopy is crucial to complete the evaluation of a child with stridor.

Flexible nasopharyngolaryngoscopy (NPL) is an invaluable tool in evaluation of a stridorous child when possible. The presence of obstructive lesions, dynamic collapse of supraglottic structures, and dysfunction of vocal cord mobility are ascertained. Caution must be used when considering awake flexible endoscopy in a child with impending airway obstruction as the potential agitation may precipitate an emergent situation. Starting with evaluation of the nasal cavities and nasopharynx, systematic evaluation of the oropharynx, hypopharynx, and the larynx must follow. The true vocal cord function must be ascertained, and the presence of collapse of supraglottic structures must be documented. Signs of gastroesophageal reflux disease (GERD) should be noted including posterior glottic edema and edema/erythema of the arytenoids. Double pH probe studies, esophageal biopsy, and radionuclide studies can then further corroborate reflux findings on endoscopy.

Rigid laryngotracheobronchoscopy is the standard for evaluating a child with stridor. In anticipation of performing the procedure, it is crucial for the anesthesia team to coordinate with the endoscopist the plan for airway management during the procedure. Intravenous steroids, such as dexamethasone 0.5 to 1 mg/kg should be given in anticipation of airway edema after instrumentation. Prior to inserting the bronchoscope, topical lidocaine should be sprayed on the larynx and into the trachea to decrease airway reactivity and to prevent laryngospasm intraoperatively and on awakening.

The operative table must be carefully prepared with an age-appropriate bronchoscope and two sizes smaller in situations of anticipated airway stenosis. Additionally, appropriate pharyngeal, laryngeal, and bronchial rigid suctions, different size endotracheal tubes, and laryngoscopes—either Parsons type or anesthesia blades such as Miller or Phillips blade—must also be available. Decide whether the procedure is to be done under spontaneous ventilation, paralysis, or jet ventilation. Spontaneous respiration is ideal in that vocal cord function and dynamic compression can be evaluated. Maintaining spontaneous ventilation is also safer in the event that the airway is considered tenuous and/or there is risk of losing an airway. If possible severe stenosis is suspected, one can avoid injury from a rigid bronchoscope by substituting suspension micro-direct laryngoscopy and bronchoscopy with a Hopkins rod telescope under jet ventilation. The airway can be sized by intubating with a cuffless endotracheal tube and documenting the size at which an air leak is appreciated at less than 20 cm water pressure.

Differential Diagnosis

The differential diagnosis for a child with stridor is extensive, as seen in Table 89.1. Because an exhaustive review of all possible etiologies is impractical given the limitations of this chapter, the following discussion focuses on the five most common etiologies: laryngomalacia, vascular anomalies, laryngotracheitis, vocal cord immobility, and subglottic stenosis. The reader is referred to other chapters in this textbook that discuss most of the other etiologies.

Laryngomalacia

Laryngomalacia is the most common etiology for stridor in infancy. Laryngomalacia is posited to be due to immature cartilages and/or immature neuromuscular tone of the

TABLE 89.1 DIFFERENTIAL DIAGNOSIS: STRIDOR IN A CHILD

Congenital
Laryngomalacia, laryngocele, saccular cyst, laryngeal web/atresia, subglottic cyst, subglottic stenosis, tracheomalacia, tracheal web/stenosis, vascular anomalies, complete tracheal rings, thymic cysts

Infections
Retropharyngeal abscess, epiglottitis, angioedema, viral laryngotracheobronchitis, bacterial tracheitis

Neoplasms
Vascular tumors—hemangiomas, lymphatic/venous/arterial malformations, recurrent respiratory papillomas, thyroid tumors, mediastinal tumors

Other
Vocal cord immobility, foreign body, laryngeal fracture, intubation trauma-cricoarytenoid dislocation

larynx leading to obstruction of the supraglottis. Several classification systems exist for laryngomalacia based on severity or location (1,2). Based on an anatomic designation, the sites of obstruction can be due to inward collapse of the aryepiglottic folds, long tubular epiglottis that curls on itself, anteromedial collapse of the corniculate and cuneiform cartilages, posterior inspiratory displacement of the epiglottis against the posterior pharyngeal wall or inferior collapse toward the vocal folds, and/or short aryepiglottic folds (3).

Diagnosis of the condition is based primarily on history and physical examination findings. Patients usually present with onset of stridor that tends to worsen with crying, feeding, or in supine position within first few weeks of life. GERD has been shown to be frequently associated with laryngomalacia (4). Symptoms of GERD should be elicited including frequent spit-ups, recurrent emesis, and back arching after feeds. More severe laryngomalacia can cause weight loss and failure to thrive with or without cyanotic episodes, and this history must be attained.

On physical examination, high-pitched inspiratory stridor is the classic presentation. Suprasternal and/or substernal retractions suggest more severe obstruction. Flexible endoscopy in clinic on an awake child can confirm the diagnosis. Features of laryngomalacia including prolapse of the epiglottis, arytenoids, and supraglottic edema must be noted. Signs of reflux must also be documented (Figs. 89.1 and 89.2).

Fortunately, the natural history of laryngomalacia is spontaneous resolution over the first 1 to 2 years of life. Medical management with aggressive acid suppression therapy is often all that is necessary to control the symptoms and signs. However, increased severity of obstruction with failure to thrive, cor pulmonale, and/or cyanotic episodes prompts surgical intervention. Supraglottoplasty, done with either CO_2 laser or "cold" with microlaryngeal instruments, should address specific areas of collapse or in releasing areas of constriction such as tight aryepiglottic folds. Rarely is tracheotomy necessary.

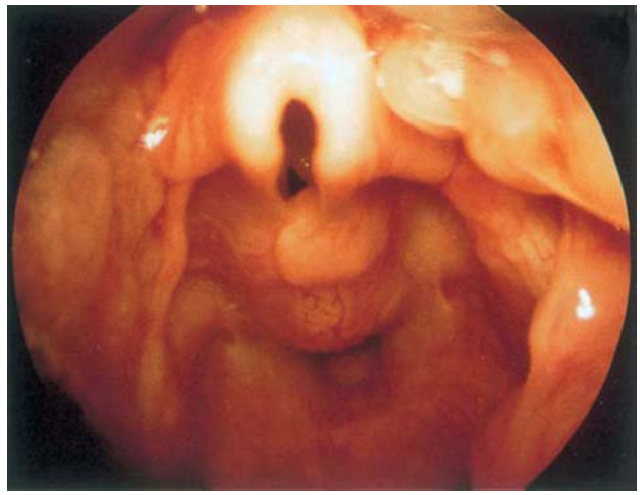

Figure 89.1 Endoscopic view of laryngomalacia during expiration.

Vascular Anomalies

Vascular anomalies that cause stridor in a child include aberrant right subclavian artery, high-riding innominate artery, pulmonary artery sling, and vascular rings and slings. An aberrant right subclavian artery is the most common congenital vascular anomaly. Although the majority of infants with this congenital vascular anomaly present with dysphagia lusoria due to the retroesophageal course of the artery, some may present with stridor. This diagnosis is often made with a barium esophagram that reveals a filling defect in the esophagus. It is confirmed with findings

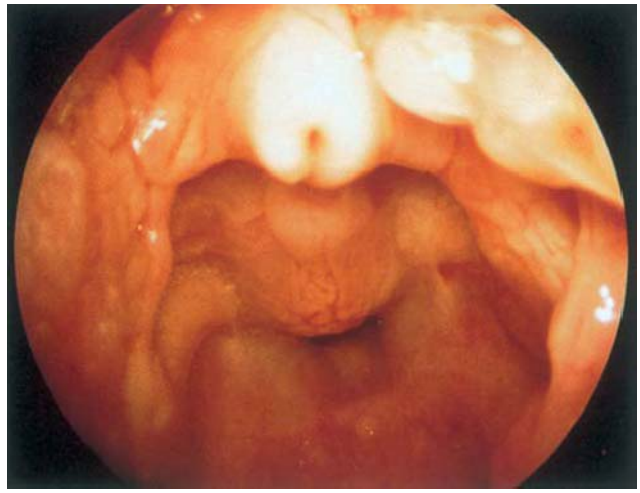

Figure 89.2 Endoscopic view of laryngomalacia during inspiration with folding inward of the epiglottis, shortened aryepiglottic folds, and collapse of the cuneiform cartilages completely obstructing the laryngeal introitus.

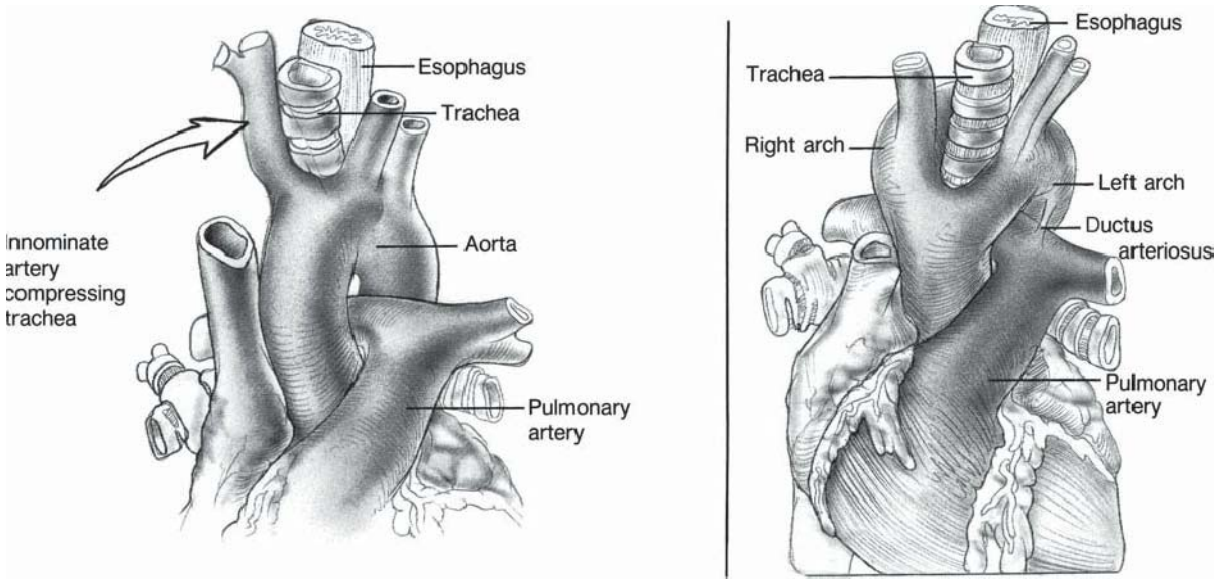

Figure 89.3 Vascular anomalies causing tracheal compression.

on CT angiography (CTA), MRI, or magnetic resonance angiography (MRA). Surgical correction via a right thoracotomy approach is recommended for symptomatic patients and has been to shown to be highly successful (5).

An aberrant course of the innominate artery commonly causes compression of anterior tracheal wall but rarely is symptomatic enough to warrant surgical intervention. In symptomatic children, expiratory, biphasic stridor, "recurrent croup," and/or recurrent pneumonia occur. Bronchoscopy demonstrates pulsatile compression of the anterior tracheal wall. Applying pressure on the anterior tracheal wall with the distal tip of the rigid bronchoscope may diminish the brachial pulse. Diagnosis can be confirmed with CTA, MRI, or MRA. Treatment is expectant in most cases. With severe symptoms, arteriopexy to the sternum is effective (6) (Fig. 89.3).

Lastly, a pulmonary artery sling or vascular ring can also present with stridor. The two most common types of complete vascular rings, double aortic arch and right aortic arch with left ligamentum arteriosum, make up nearly 85% to 95% of all vascular rings (7). Double aortic arches occur due to persistence of embryonic bilateral fourth branchial arch vessels and dorsal aortas. Pulmonary artery slings occur when the left main pulmonary artery arises as a branch of the right pulmonary artery, instead of from the main pulmonary artery due to an abnormality of the sixth branchial arch artery development. Pulmonary artery slings are often associated with complete tracheal rings (Fig. 89.4).

In general, both of these anomalies present with signs of tracheal compression such as biphasic stridor. In addition, chronic cough, recurrent pneumonias, and recurrent croup can occur. Symptoms of dysphagia with a double aortic arch tend to be a more frequent presentation of older children with milder tracheal compression who present later in life. Always suspect vascular anomalies in an infant with atypical "asthma" or in children with severe symptoms associated with respiratory tract infections out of proportion to what is expected; especially when a history of noisy breathing since birth is elicited.

Chest radiographs can reveal compression of the trachea, an abnormally positioned aortic arch, and/or hyperinflation of the right lung with anomalous left pulmonary artery. Since a right-sided aortic arch is almost always present in a vascular ring, identifying this on a chest radiograph is critical. A right-sided aortic arch courses over the right main stem bronchus instead of the usual left main stem bronchus as in a left-sided aortic arch. Thus, the arch

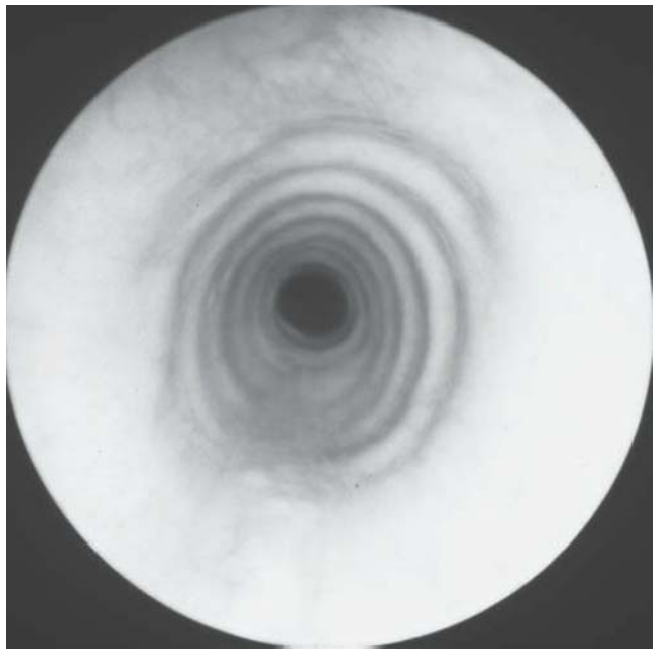

Figure 89.4 Endoscopic view of complete tracheal rings.

itself may not necessarily occupy the right hemithorax. The normal left-sided aortic arch displaces the carina to the right as it courses over the left main stem bronchus. This slight deviation in the normal tracheal air shadow can often be appreciated on the anteroposterior (AP) or posteroanterior view of the chest radiograph. In a right-sided aortic arch, the carina deviates to the left instead as the aorta courses over the right main stem bronchus.

A barium esophagram performed in patients with dysphagia may reveal a filling defect resulting from posterior vascular compression. Echocardiograms readily reveal anomalous vascular structures. CT/CTA or MRI/MRA generally confirms the diagnosis in cases of vascular rings or pulmonary artery sling. Lastly, bronchoscopy may be used to diagnose pulsatile vascular compression and cases of complete tracheal rings associated with a pulmonary artery sling.

While milder vascular anomalies may be observed closely, vascular rings and pulmonary artery slings generally require surgical repair. Prolonged intubation, reflex apnea, and failure of medical treatment are absolute indications for surgical repair. In addition, severe dysphagia and failure to thrive, recurrent bronchopulmonary infections, associated asthma/cystic fibrosis, or exercise intolerance are relative indications for surgical repair. Fortunately, patients without other significant comorbidities or associated anomalies have favorable surgical prognosis, and symptoms tend to resolve after repair.

Laryngotracheobronchitis

Viral laryngotracheobronchitis, or croup, is the most common infectious source of stridor in children. Although the most common cause is parainfluenza virus type 1, other viruses such as respiratory syncytial virus, influenza A, and parainfluenza types 2/3 can also cause viral croup. Most common age of occurrence is from age 6 months to 3 years, although it is rare in infants less than a year of age. When it occurs in a child less than 1 year of age, a possible underlying airway abnormality or stenosis should be suspected.

The diagnosis is largely based on history and physical examination findings. The usual course of illness begins with 2- to 3-day prodrome of upper respiratory illness–type symptoms progressing to barking cough and inspiratory stridor. If there is presence of high fever, rapid progression of symptoms, drooling, and odynophagia, epiglottitis should be considered, and rapid evaluation and treatment should be initiated. On examination, the child will exhibit a fairly prototypical barky cough, stridor, and varying degrees of increased work of breathing.

A high-kilo voltage soft tissue neck radiograph, AP view, may demonstrate the classic "steeple" sign, depicting the narrowing of the subglottis. Lateral soft tissue radiography may demonstrate an edematous epiglottis (thumbprint sign) seen in epiglottitis, which can sometimes present with early similar clinical symptoms as croup. Flexible NPL can be safely performed in a clinically stable child and sometimes reveals an edematous subglottis visualized through abducted vocal cords.

Laryngotracheobronchitis, is usually self-limited and is most often managed conservatively as an outpatient. However, with increased work of breathing, hospital admission and close observation may be necessary. Humidification, blow-by oxygen supplementation, and continuous pulse oximetry can be used in management. Corticosteroids, such as dexamethasone at dose of 0.5 to 1 mg/kg, are prescribed to decrease subglottic edema. Lastly, nebulized racemic epinephrine rapidly reduces subglottic inflammation while steroids are taking effect; however, the effects are transient and children often develop rebound edema. Rarely do the children develop worsening stridor and respiratory distress requiring intubation. Heliox, a mixture of helium and oxygen, may supplant endotracheal intubation by reducing the work of breathing. If necessary, nasotracheal intubation with an endotracheal tube one size smaller than expected for the child's age must be used. Failure to extubate despite observation and medical management should prompt direct laryngoscopy with bronchoscopy to evaluate for underlying subglottis stenosis or other airway anomalies.

Vocal Cord Immobility

Vocal cord immobility is the third most common congenital cause of stridor, occurring in nearly 10% of the cases. Causes of vocal cord immobility include neurologic causes such as Arnold-Chiari malformation or hydrocephalus, trauma from stretch injury to recurrent laryngeal nerve during birthing process, or trauma from injury to nerve during cardiac surgery.

Children with unilateral vocal cord immobility usually present with a weak voice and signs of aspiration. With bilateral vocal cord immobility, inspiratory stridor and an abnormal cry are also prominent. The diagnosis may be made with flexible NPL in an awake child although this assessment is often more challenging than is recognized. Vocal fold immobility is sometimes difficult to distinguish from movement resulting from a Bernoulli effect. Similarly, paresis may be over diagnosed in a sedated child. Children with significant laryngomalacia or supraglottic hyperfunction may simply obscure adequate visualization of their vocal cords. Finally, "pseudoparalysis" or cricoarytenoid joint ankylosis may be misdiagnosed as vocal fold immobility.

Such diagnostic challenges not withstanding, once diagnosed, further evaluation depends on suspected etiology. Imaging of the head down to the chest along the entire course of the recurrent laryngeal nerve might be necessary to identify neurologic or cardiovascular anomalies. Although more logistically challenging in children, laryngeal EMG may assist with the diagnosis in difficult cases and often provides information needed to make clinical management decisions. As more experience is gained with laryngeal EMG in children, it is likely that the role of this intervention will expand not only in cases with diagnostic uncertainty but as a means of providing objective data to assist in management decisions.

If an obvious cause of immobility is identified, treatment of that cause often leads to return of normal vocal fold movement such as decompression of a Chiari malformation. In idiopathic cases, observation is recommended since most cases resolve within first 2 years of life. Delayed resolution after several years has been reported in children and the precise timing beyond which spontaneous recovery of vocal fold movement in children cannot occur is unknown. If there is significant difficulty in maintaining an adequate airway in cases of bilateral vocal cord immobility, tracheostomy may be temporally needed. If the immobility is permanent, various surgical procedures are available to improve airway patency. In cases of bilateral immobility, vocal cord lateralization, excisional procedures such as laser arytenoidectomy, posterior cordotomy, and reinnervation procedures are all potential options pending the specific circumstances of the child.

Subglottic Stenosis

Subglottic stenosis is a congenital or acquired narrowing of the subglottis. The subglottis is the area extending from the lower surface of the true vocal cords to the inferior margin of the cricoid cartilage. The narrowest part of an infant's airway is the subglottis and it normally measures 4 to 7 mm. Less than 4 mm in size in a newborn or 3.5 mm in a premature infant is diagnostic of subglottic stenosis (Fig. 89.5).

Acquired subglottic stenosis is the most common type and requires treatment more often largely because of improved perinatal intensive care and survival of premature infants who required prolonged endotracheal intubation for premature lung disease. Nearly 90% of acquired cases are due to prolonged endotracheal intubation. Risk factors for development of subglottis stenosis include prolonged duration of intubation, overly large endotracheal tube, recurrent intubations, and presence of infection during course of intubation. Other causes of acquired subglottic stenosis include blunt, penetrating, or caustic laryngeal trauma. Iatrogenic damage to subglottis from previous cricothyroidotomy, high tracheostomy, or laser surgery can also be causative.

On the other hand, congenital subglottic stenosis is diagnosed when all other causes have been excluded. It is thought to occur due to failure of the laryngeal lumen to completely recanalize during embryogenesis. Congenital subglottic stenosis can be divided into a membranous type when there is mainly soft tissue occluding the lumen or a cartilaginous type when it is due to abnormalities of cricoid (elliptical cricoid), which narrow the lumen.

Presenting symptoms depend on the severity of the stenosis. If severe, audible biphasic stridor possibly with signs of respiratory distress and increased work of breathing are seen. In milder cases, the child may contract recurrent episodes of croup with or without feeding issues. A thorough birth history must be documented and includes prematurity, need for intubation, and any associated comorbidities. Any feeding difficulties and failure to thrive should be noted. Signs of reflux should be sought.

On physical examination, observation of the patient's overall body habitus and breathing patterns provides useful

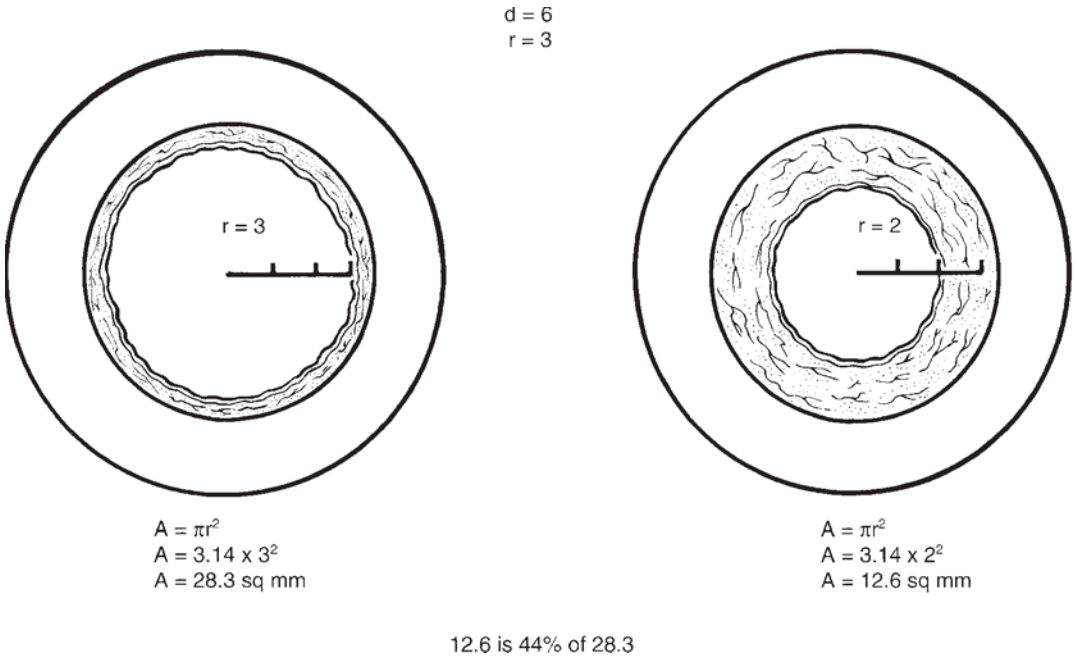

Figure 89.5 The normal newborn subglottic larynx has a diameter of 5 to 7 mm and a cross-sectional area of approximately 28.3 mm^2. Only 1 mm of edema reduces the area to 12.6 mm^2, 44% of normal. (From Holinger LD. Evaluation of stridor and wheezing. In: Holinger LD, Lusk RP, Green CG, eds. *Pediatric laryngology and bronchoesophagology.* Philadelphia, PA: Lippincott-Raven, 1997:41–48, with permission.)

diagnostic clues. Auscultation of chest and neck may reveal biphasic stridor and the voice may be hoarse or weak. Flexible NPL may allow for adequate visualization of the subglottis through abducted vocal cords. Diagnosis using a flexible fiberoptic laryngoscope in a nonsedated child may be challenging as a prominent anterior cricoid cartilage lamina may be confused with subglottic stenosis. In such cases, advancing the flexible endoscope through the vocal cords is not recommended due to the risk of inducing laryngospasm and life-threatening airway obstruction.

CT and MRI, although rarely necessary, may help to quantify the length of the stenosis and, hence, aid in surgical planning. The gold standard for evaluation of the subglottis is direct laryngoscopy and bronchoscopy, which also have the advantage of identifying secondary airway lesions. Sizing of the airway with endotracheal tubes according to the Myer-Cotton staging system is recommended. This staging system describes the percent narrowing of the subglottis as determined by various sized endotracheal tubes with one of four grades. Grade I is less than 50% obstruction, grade II is between 51% and 70% obstruction, grade III is 71% and 99% obstruction, and grade IV is no detectable lumen (8).

Management of stenosis is dependent on severity of stenosis and symptomatology of the child. In general milder stenosis, Cotton-Myer grade I/II can be managed medically and with close observation. GERD therapy is prescribed as it has been shown to reduce edema and decrease the number of croup episodes. More severe stenosis, grades III/IV usually necessitates surgical intervention. Surgical options depend on the type, length, and degree of stenosis in addition to patient characteristics such as overall general medical condition, swallowing ability, presence of aspiration, age, and weight of the child. Options include tracheostomy, endoscopic dilation, and open procedures. Open procedures can include expansion procedures such as anterior or posterior cricoid split or both with cartilage grafting or cricotracheal resection.

Management

Management of stridor in general depends on the severity and acuity of the airway distress. While preparations are underway for airway management, the patient must be evaluated expeditiously and vital signs must be assessed. Initial measures include determining the patient's oxygen saturation and initiating humidified supplemental oxygen keeping in mind the potential for CO_2 retention as a possibility even if the patient exhibits normal oxygen saturation. Appropriate medical therapy must be initiated including steroids, intravenous antibiotics, and nebulized racemic epinephrine depending on the working diagnosis. Once clinically stable, the patient should be transferred to an appropriate monitored unit.

When there is impending obstruction, preparations must be made for intubation. If possible, intubation should proceed in a controlled environment with an anesthesia team present in the operating room and with the operative plan clearly discussed with all members of the team. The size of an endotracheal tube for intubation should be age appropriate and is determined by the formula: (age + 4)/4 except situations of airway stenosis where the smallest size adequate for oxygenation and ventilation should be used. Rarely is emergency tracheostomy necessary. Cricothyroidotomy is not recommended in pediatric patients due to the small size of the cricothyroid membrane and the increased incidence of laryngeal injury.

ASPIRATION

Aspiration is the penetration of oral and nasal secretions, food particles, or refluxate through the vocal cords. A small amount of aspiration occurs normally and is not considered pathologic provided effective clearance mechanisms are intact. However, when the amount aspirated overwhelms clearance and defense mechanisms, bronchopulmonary complications result.

A normal swallowing mechanism includes three phases—oral, pharyngeal, and esophageal. The oral phase includes the oral preparatory phase and the oral transport phase. The oral preparatory phase involves formation of a bolus and the transport phase involves propulsion of the bolus from the mouth into the oropharynx. The pharyngeal phase is a complicated process of movement of the bolus from the oropharynx into the esophagus that includes soft palate elevation to close the nasopharynx, laryngeal elevation, glottic closure, contraction of the pharyngeal constrictors, and relaxation of the cricopharyngeus to allow passage of bolus. Lastly, the esophageal phase is the transport of the bolus from the esophagus into the stomach. Normal swallow function is essential to prevent aspiration. In addition, protection is also provided by glottic closure that depends on normal function of the epiglottis, vocal cords, and aryepiglottic folds.

Diagnosis

Diagnosis of a child with aspiration begins with an accurate history. Aspiration often presents with cough and choking with feeding. With silent aspiration, a protective cough reflex is absent. Depending on the etiology of aspiration, the child may also present with hoarseness, stridor, or dysphagia. There may be a history of recurrent pneumonia or chronic respiratory illness. The medical history should include recent surgeries, traumas, comorbidities, and a complete birth history. Risk factors for aspiration include prematurity, central nervous system anomalies, and anatomic abnormalities of the aerodigestive tract.

A thorough head and neck examination is performed with attention to cranial nerve function. Examination of the oral cavity should focus on both form and function of the tongue and palate. Note any masses or lesions that are present. Facial dysmorphisms and any neurologic deficits must be identified.

Endoscopy

Once a thorough history and physical examination is completed, an endoscopic evaluation can diagnose aspiration and, in addition, may reveal the etiology in many cases. Simple flexible NPL can evaluate vocal cord mobility and identify obvious structural abnormalities such as a laryngeal cleft. The nasopharyngolaryngoscope, in addition, can be used to perform a functional endoscopic evaluation of swallowing, or FEES, to directly evaluate swallow mechanism. The scope is positioned at the level of the soft palate and used to visualize the hypopharynx and the larynx while the patient is fed various consistencies of colored food. Several parameters are recorded including laryngeal penetration, aspiration, pharyngeal pooling, and premature spilling. While this technique is advantageous in that it avoids radiation and is relatively inexpensive, the success of the procedure depends largely on the skill of the physician and speech language pathologist and most importantly depends on the patient's cooperation. FEES is also considered more sensitive in detecting microaspiration. The most distinct limitation of FEES is the "white out" that precludes visualization of the swallow itself. The interpretation of the study relies on what is visualized immediately before and after the swallow. FEES is not physiologic, which is another limitation of the technique. When sensory testing to assess the laryngeal adductor reflex (LAR) is included, the study is referred to by the acronym FEEST.

Operative endoscopy is often necessary for further diagnosis. Direct laryngoscopy, bronchoscopy, and esophagoscopy can be performed to evaluate for structural abnormalities of the aerodigestive tract such as laryngeal clefts, tracheoesophageal fistulas (TEFs), or strictures. Bronchial alveolar lavage can be performed to assess for lipid-laden macrophages suggestive of aspiration and esophageal biopsy can reveal signs of reflux esophagitis.

Radiology

Radiographic studies can aid in the diagnosis of aspiration and include videofluoroscopic swallow study, scintigraphy, and upper gastrointestinal (UGI) series. Videofluoroscopic swallow study is performed in a fluoroscopic unit. The patient is in an upright position and is fed different consistencies of food with small amounts of barium while the phases of swallowing are evaluated under fluoroscopy by a speech language pathologist. This study is considered the "gold standard" physiologic means by which cervical swallowing function is assessed in children suspected of aspiration. All phases of swallowing are assessed. Esophageal abnormalities such as cricopharyngeal opening disorders, esophageal wall pouches, or even regurgitation can be documented and the study can be extended to assess for gastric outlet obstruction. UGI series nicely defines the esophageal anatomy and may identify anomalies that predispose to aspiration. Lastly, radionuclide scintigraphy is performed by having the patient swallow a small amount of water with ^{99m}Tc and the radioactive tracer that enters the lungs is quantified as a percentage of the total radioactive count. It is also quite useful in assessing rate of gastric emptying.

Other studies that may be useful in specific situations include CT or MRI to evaluate the brain and brainstem. Manometry may be indicated to evaluate for aspiration when esophageal motility disorders and manometric abnormalities of the upper esophageal sphincter tone are suspected. Lastly, dual pH probe testing is the "gold standard" by which to diagnose GERD when aspiration "from below" is suspected.

TABLE 89.2 DIFFERENTIAL DIAGNOSIS: ASPIRATION IN A CHILD

Congenital	Neurologic	Other
Laryngeal cleft	Hypotonia	Vocal cord immobility
Tracheoesophageal fistula	Encephalopathy	Cleft palate
Esophageal atresia/webs/duplications, vascular rings, achalasia	Anoxic brain injury Arnold-Chiari malformation Muscular dystrophies Cerebral palsy	Neoplasm GERD Foreign body Postsurgical

Differential Diagnosis

The differential diagnosis of a child with aspiration is listed in Table 89.2. Neurologic dysfunction and various aerodigestive anomalies account for a significant number of cases of aspiration in children. Neurologic dysfunction may result from diffuse injury to the brain during delivery, trauma, or perinatal infections. Degenerative diseases such as amyotrophic lateral sclerosis, myasthenia gravis, or spinal muscular atrophy and peripheral nerve disorders, especially involving cranial nerves can also cause aspiration. Lastly, pharyngeal hypotonia, whether from muscular dystrophies, cerebral palsy, or other muscular disorders can lead to poor pharyngeal tone and poor control of swallowing mechanics.

Laryngeal Clefts

Laryngeal clefts are congenital anomalies that result from failure of the airway to separate from the esophagus during embryogenesis. Laryngeal clefts are graded as grade I involving only the interarytenoid muscle, grade II involving part of the cricoid, grade III involving the entire cricoid, and grade IV extending the cleft into the trachea (9). Laryngeal clefts are often associated with various syndromes such as Pallister-Hall or Smith-Lemli-Opitz, which must be considered during evaluation. The typical presentation of a child with a laryngeal cleft is aspiration in milder cases. Cyanotic episodes with feeding and recurrent pneumonias

are seen in more severe cases of higher grade. Diagnosis is confirmed with direct laryngoscopy and bronchoscopy by palpating the interarytenoid musculature in type I clefts when there is no obvious cleft visible. Confusion in the literature exists regarding the precise means by which to distinguish a type I laryngeal cleft from a deep interarytenoid notch. Further adding to the diagnostic uncertainty is the reported increased incidence of reflux aspiration in both. Fortunately, the treatment approach is similar in both and depends largely on the consequences of either anomaly. This relegates much of the discussion to academic interest alone. The major dilemma arises due to a natural spontaneous resolution of symptoms with growth and development in both conditions. When this fact is coupled with the reality that surgically converting a high-grade type III or IV cleft into a type I cleft is often reported as a "surgical success," it is sometimes difficult to accept aggressive surgical recommendations for mildly symptomatic infants. Judicious assessment and conservative algorithms are prudent. Milder clefts can be observed and treated conservatively. If needed, endoscopic repair is often successful. With advanced clefts, open surgical repair is often necessary either via a laryngofissure or posterolateral approach with extension into trachea.

Tracheoesophageal Fistula

Tracheoesophageal fistula, TEF, is another congenital anomaly that results in aspiration due to an abnormal connection between the trachea to the esophagus. By far, the most common type of deformity is esophageal atresia with a concomitant distal TEF in nearly 90% of the cases. Less common types include isolated esophageal atresia without TEF, isolated TEF, and esophageal atresia with proximal or proximal and distal TEF. Most cases are diagnosed immediately after birth due to severe aspiration and life-threatening perinatal complications. TEFs are often associated with syndromes such as VACTERL and Down syndrome, the latter of which includes other developmental anomalies such as congenital cardiac disease. As such, presence of a TEF must prompt a thorough examination of the child for comorbidities. Postnatal diagnosis can occur with chest radiography revealing the absence of a gastric bubble due to esophageal atresia. In addition, insertion of nasogastric tube may be complicated by coiling in the mediastinum. CT and MRI can also be used for diagnosis. Surgical repair is required with TEF and may have to be deferred until concomitant comorbidities such as prematurity, pneumonia, and low birth weight are stabilized.

Management

Medical Management

Upon diagnosis of aspiration, multidisciplinary care must be instituted including the following pediatric specialists; pulmonologists, speech–swallow therapists, otolaryngologists, and depending on etiology, neurologists, geneticists, intensivists, and pediatric surgeons. Initial management involves treating underlying pneumonia and respiratory complications. Appropriate antibiotics are given and aggressive pulmonary toilet is instituted as directed by pulmonologists and respiratory therapists. Control of aspiration is necessary and all oral feeding must be discontinued while evaluation and treatment is in progress. Nasogastric tube and enteral feeding are both options but do not completely eliminate aspiration. Gastrostomy or jejunostomy tube feeding is necessary when a protracted course is anticipated. Control of sialorrhea with anticholinergics and/or antihistamines may be useful. The side effects of these medications must be discussed with the family prior to institution. Recently, ultrasound-guided botox injections into the submandibular and parotid glands have successfully decreased salivary production and subsequent salivary aspiration. This results in temporary relief for 3 or more months and should be considered as a minimally invasive alternative to surgery, especially in younger children under the age of 7 years whose swallowing function is expected to improve.

Surgical Management

Surgical procedures for aspiration can be divided into two main subsets: control of sialorrhea and laryngeal control of aspiration. Surgery to control sialorrhea either reduces salivary production or changes the location where saliva enters and includes a myriad of procedures such as salivary duct rerouting, excision of salivary glands, or any combination of the above procedures. See Table 89.3. Laryngeal control of aspiration can be achieved with vocal cord medialization, tracheostomy, laryngeal closure, and laryngotracheal separation (10).

Control of Sialorrhea

A complete review of all procedures that can be used for control of sialorrhea is not feasible within the context of this chapter. However, some commonly performed procedures that are highly successful are described below.

Submandibular gland duct rerouting is achieved by rerouting the Wharton ducts to the tonsillar fossae. Initially, a tonsillectomy is performed. Next, the Wharton ducts are identified, dissected, and then sutured to the tonsillar fossae. The advantages of this procedure include avoidance of external incisions and prevention of xerostomia. However, since the secretions are not decreased but just rerouted posteriorly, this procedure may increase aspiration in a child that is neurologically incompetent and/or is already at risk of aspiration for other reasons. Excision of sublingual glands in conjunction with submandibular duct rerouting is effective in controlling sialorrhea and prevents the complication of ranula formation (11).

Excision of bilateral submandibular glands with or without parotid duct ligation has also been shown to be highly successful in decreasing sialorrhea (12). Advantages

TABLE 89.3 SURGICAL MANAGEMENT OF SIALORRHEA

Surgery	Advantages	Disadvantages
Submandibular gland duct rerouting/ Parotid duct rerouting	Avoidance of external incisions Unlikely xerostomia	May increase aspiration Without sublingual gland excision, risk of ranula
Excision of sublingual glands	Internal approach possible	Insufficient control unless combined with other procedures
Excision of submandibular glands	Decreased resting flow Good control of sialorrhea Internal approach possible	External scar
Excision of parotid glands	Decreased stimulated flow Good control of sialorrhea	External scar
Parotid duct ligation	Decreased stimulated flow Avoidance of external incisions	Risk for dental caries Risk of xerostomia when combined with other procedures Risk for sialocele, parotitis
Transtympanic neurectomy	Technically easy, fast	Predictable return of salivary function; usually requires revision

include decreased resting salivary output. If the parotid ducts are also ligated, stimulated flow from the parotid glands is decreased. As the amount of saliva is decreased, however, the risk of dental caries and xerostomia increase. In addition, sialoceles, parotitis, and external scars can complicate this surgery (13).

Laryngeal Control of Aspiration

Vocal cord medialization can be achieved either by vocal cord injection or by medialization procedures. Vocal cord injections with temporary fillers such as resorbable synthetic polymers (sodium carboxymethylcellulose) combined with water and glycerin, a bovine gelatin agent (gelfoam), hyaluronic acid, freeze-dried micronized acellular human cadaveric dermis, cross-linked bovine collagen, or semipermanent injection with fat, fascia, synthetic calcium hydroxylapatite, or polytetrafluoroethylene can be used to medialize vocal cords to decrease aspiration. The procedures are highly effective especially in cases of vocal cord immobility. Alteration of the laryngeal framework by using implants externally remains the criterion standard for long-term medialization of the vocal cords. A recent study, however, failed to demonstrate improved outcomes with aspiration following framework surgery as compared to vocal cord injections. Advantages of endoscopic vocal cord injections include avoidance of external scars and reversibility in cases of expected vocal cord function recovery (14).

Tracheotomy is an option for patients with aspiration; however, inherent to the procedure is possible worsening of aspiration. Tracheotomy is primarily useful in providing access to suction and for airway management in cases that otherwise would require prolonged endotracheal intubation. In addition, cuffed tubes may decrease the volume of secretions that enter the lower airway. An inflated cuff decreases the phonatory capacity of the child and along with the tracheostomy tube impairs laryngeal elevation due to tethering. Together these factors may worsen aspiration. Cough may also be impaired, which compromises the primary pulmonary clearance mechanism that prevents pneumonia. For these reasons, tracheostomy should be viewed as a temporizing measure until more definitive control of aspiration can be achieved and should be recommended judiciously.

Definitive approaches to aspiration include laryngeal closure and laryngotracheal separation. Laryngeal closure may be achieved by suturing the glottis or supraglottis temporarily until swallowing function improves and aspiration decreases. Procedures described in the literature include closure of the false vocal folds (15) while preserving separation of the true vocal cords and arytenoids. Alternatively, closure of the glottis and supraglottis using hinged flaps from true and false vocal folds has also been described (16). Laryngotracheal separation completely isolates the airway from the digestive tract and, hence, eliminates aspiration. It has been shown to be 90% to 100% successful in eliminating aspiration (17). The procedure divides the trachea into two segments; the proximal trachea with the larynx is oversewn into a blind pouch and the distal trachea is converted into tracheostomy. Although vocalization is no longer an option, the patient is able to continue oral feeding and maintain an airway without aspiration. The procedure is also potentially reversible although the underlying neurologic condition of the child that required the procedure may preclude reversal. When considering these later interventions, the clinician must be sensitive to the family's perception of the utility of the child's voice. Although to a clinician, the child may be deemed nonverbal and, hence, in no need of vocal capacity, many of these families consider the child's voice critical in alerting them to pain and discomfort. Anecdotally, it is rare that the families of these children are comfortable eliminating the capacity for phonation.

COUGH

For the Otolaryngologist, it Cannot Just be About Sinusitis

There are many ways that the symptom of cough can be conceptually approached. Much of the conceptualized approach is predicated upon the specialized orientation and training of the health care provider. Emergency room physicians focus on ruling out conditions that require urgent diagnosis and treatment. At the top of their lists are diagnoses such as pneumonia and pulmonary embolus. Gastroenterologists search for extrapulmonary causes of cough such as GERD and primary digestive abnormalities such as esophageal diverticula. Conversely, pulmonologists tend to focus on lower airway causes of cough such as asthma and tracheobronchomalacia. Although allergists have evolved into specialists that overlap considerably with pulmonologists with respect to reactive airway disease, they also explore otolaryngologic diagnoses such as sinonasal etiologies albeit with a greater focus on allergic drivers of inflammation rather than infectious or anatomic drivers. Primary care physicians screen all of the organ systems and often base suspected diagnoses on history alone while attempting to confirm their suspicions by prescribing "shot-gun" empiric medications directed at the most likely causes.

So where does this position the niche of the otolaryngologist? At the very least, an otolaryngologist is expected to identify or eliminate upper aerodigestive sources of cough. Having spent a career in a pediatric tertiary care center, patients are often referred following a general otolaryngology evaluation. After review of many such consultation reports, it has not been uncommon to find the following sole conclusion; "This is a patient with chronic cough who does not have rhinosinusitis as the underlying etiology. Alternative causes should be investigated." Although this may help the referring physician and patient to some degree, it is certainly not the model consultation to be emulated.

The deft otolaryngology consultant understands two objectives. First, what patients and referring physicians really seek is the etiologic identification and treatment of cough. To the extent possible, these should be the consultant's goals as well. Second, developing at least a working knowledge of nonotolaryngologic causes of cough is critical. This is especially true in cases where the cough is recurrent, as opposed to chronic, and not necessarily present on the day of the otolaryngology consultation.

A common chief complaint that exemplifies this scenario is "recurrent croup." Often such patients never had croup at all but had recurrent cough of a nonproductive and barky nature. A second reason the otolaryngology consultant must be mindful of other causes of cough is that it is not uncommon for chronic cough to result from more than one cause. The literature reports that chronic cough has more than 20 causes, and in up to 62% of cases more than one cause is identified (18). Finally, one often cannot definitely rule in or rule out certain head and neck causes of cough without also considering nonotolaryngologic etiologies. Because separate chapters are included in this book on nearly all of the etiologies to be identified, this chapter's focus is on the diagnostic approach needed to identify the underlying cause(s) of cough. Discussions of individual etiologies are limited to particular mechanisms and aspects specific to cough. Similarly, treatment recommendations for the underlying causes of cough (asthma, GERD, allergic rhinitis, infectious rhinosinusitis, etc.) are mentioned but not comprehensively outlined as more detail is included in other chapters. The only detailed therapeutic treatment discussion in this chapter focuses on the treatment of cough primarily. This discussion includes a review of the most recently published evidence-based best practice guidelines by the American College of Chest Physicians (ACCP) in January 2006 (19). With these tenets in mind, this section emphasizes a multidisciplinary approach to cough. In other words, "it's just not all about sinusitis!"

Step One: Commit to Memory an Anatomic Image of Where All the Cough Receptors are Located and Use it as a Systematic Map to Direct the Evaluation

Understanding that each specialty-specific approach to cough has its own set of advantages and disadvantages, and accepting the logistical limitations of being unable to exhaust all of them, a reasonable algorithmic framework is needed. Having experience with most of these, the approach that best systematizes the evaluation is one which identifies the locations within the body of each set of cough receptors. By committing this framework to memory, the clinician can algorithmically obtain a history, focus a physical examination, and optimally select the most effective diagnostic studies.

Such structure is particularly critical for the evaluation of cough for several reasons. First, cough is one of the most common complaints for which patients seek medical attention. There are nearly 30 million physician visits for cough in the United States each year positioning cough amongst the top five for number of doctor visits (19). Second, cough may result from pathology in more than a half dozen distinct anatomic locations. Third, the empiric treatment of cough has resulted in several public health issues such as the over use of antibiotics leading to bacterial resistance. About 3.5 billion dollars are spent each year on over-the-counter (OTC) cough medications alone such as expectorants and cough suppressants (19).

Although the focus of this chapter is on clinically relevant information, it is important to review certain fundamental basic science concepts that lay the conceptual foundation for this algorithmic approach.

Step Two—Determine if Cough is Physiologic or Pathologic

Before delving into the "pathology" of cough, it is important to emphasize that, in and of itself, cough does not represent a sign of disease. To the contrary, cough is an important normal protective reflex activity. The most widely recognized neural response involved in airway protection is cough. Cough is generally characterized by a reflex-evoked modification of the breathing pattern in response to airway irritation (20). Reflex cough occurs when subsets of airway afferent (sensory) nerves are activated by inhaled, aspirated, or locally produced substances. Although an occasional cough is normal, excessive coughing or coughing that produces blood or thick, discolored mucus is abnormal.

The cough reflex has five components: (a) cough receptors, (b) afferent nerves, (c) a poorly defined cough center, (d) efferent nerves, and (e) effector muscles.

Key to cough particularly in pathology is the cough receptors. In summary, cough receptors are throughout all the airways and UGI tract as well as the pericardium and diaphragm. Specifically, receptors that activate the cough reflex are situated mainly in the proximal airways within the soft tissues and smooth muscle. It is important to bear in mind that receptors are concentrated in the larynx and carina and at other airway bifurcations. No receptors lie beyond the terminal bronchioles. Receptors are found in the nose, nasopharynx, posterior oropharynx, external auditory canals, tympanic membranes, stomach, esophagus, pleura, pericardium, and diaphragm.

Step Three—Apply the Basic Science

So what is the practical clinical significance of a basic science review of the anatomic cough receptors? From an otolaryngologist's perspective, a systematic, thorough, and sequential assessment of the nose, paranasal sinuses, nasopharynx, oropharynx, hypopharynx, larynx, external auditory canal, tympanic membrane, esophagus, trachea, carina, and main-stem bronchi must be performed. Clearly, the fact that there are primary cough receptors in every anatomic subregion considered within the primary domains of otolaryngology emphasizes two important points. First, this chief complaint encompasses arguably the broadest range of potential otolaryngology differential diagnoses. Second, the majority of the etiologies of cough are within our specialty. Referring physicians are well aware of this fact which is why otolaryngologists are consulted early, often and frequently before any other specialists.

If a head and neck assessment fails to identify a cause for cough, a screen for nonotolaryngologic etiologies should focus on cardiac, pulmonary, and gastrointestinal alternatives. In many such instances, the otolaryngologist's skill sets are ideally suited for making the diagnosis even in cases where there is no head and neck pathology. In other cases, prudent referral to specialists in cardiology, pulmonology, gastroenterology, infectious disease, or allergy is needed. Neurologic and orthopedic causes must also be considered as cough can occur with vagus neurilemomas and cranial nerve stimulation from cervical osteophytes. Although many of these causes are beyond the scope of this chapter, it is critical to never lose site of the wide range of organ systems potentially involved.

Step Four—Don't Forget Functional Etiologies—Tic Cough, Habit Cough, and More…

The last basic science reality that is important to mention is that cough can also be voluntarily initiated without stimulation from other afferent pathways. The efferent fibers of the cough reflex carry their signals from the cough center to the diaphragm and intercostal muscles through the phrenic and spinal motor nerves, respectively. The abdominal and pelvic muscles also participate in the efferent limb. This reality highlights the need to consider tic, psychogenic, or habit cough when no other organic etiology is identified. Unfortunately, this is a diagnosis of exclusion and cannot be confirmed until several different specialists have ordered costly, invasive, and extensive diagnostic tests. At times, because so many tests are obtained, several "red herrings" are found that further complicate the evaluation as they must all be pursued as well. With this conceptual framework in hand, how should the otolaryngologist proceed?

Step Five—The History…

Precisely quantifying the duration of cough is crucial. Pediatric chronic cough (i.e., cough in children aged less than 15 years) is defined as a daily cough lasting for more than 4 weeks (21). This time frame was chosen based on the natural history of upper respiratory tract infections (i.e., URTIs) in children and differs from the definition of chronic cough in adults. Cough quality may suggest an etiology, yet, surprisingly there are no published studies that rigorously compare etiologies of "dry cough" versus "wet cough." Chronic cough is subdivided into specific cough (i.e., cough associated with other symptoms and signs suggestive of an associated or underlying problem) and nonspecific cough (i.e., dry cough in the absence of an identifiable respiratory disease of known etiology). Most cough characteristics recognized as classical have not been systematically studied. Such traditional recognized cough characteristics and the etiologies they suggest are as follows:

Cough Characteristics	Etiologies Suggested
Barking/Brassy cough	Tracheomalacia (22–24) Croup (25) Habit cough (26,27)
Cough productive of casts	Plastic bronchitis (28)
Honking cough	Psychogenic (29)
Paroxysmal cough +/− whoop	Pertussis (30) Parapertussis (31) Psychogenic
Staccato cough	*Chlamydia* in infants (32)

A history of neurodevelopmental abnormalities strongly implicates aspiration as the cause of cough. Aspiration as a cause of cough was discussed in detail above (21). Finally, although cough as a side effect of medication is less common in children, review medication lists for those which may have cough as a side effect. This etiology is far more prevalent in adults who are on medications such as angiotensin-converting enzyme (i.e., ACE) inhibitors.

Step Six—The Physical Examination...

Specific causes of cough are suggested by several physical findings. Pulmonary etiologies are suggested by auscultatory findings such as wheezing and crepitations. Physical signs of viral URTIs are significant in three ways. First, nasopharyngeal cough receptors are stimulated by copious viscous secretions in the nasopharynx. Second, endobronchitis is not uncommonly seen in the latter stages of a viral respiratory tract infection. Finally, 80% of childhood asthma exacerbations are due to viral URTIs. Similarly, cardiac anomalies and chest wall deformity clearly suggest specific etiologies of cough. Digital clubbing and failure to thrive markedly raise the index of suspicion for cystic fibrosis.

Step Seven—Which Diagnostic Tests Should be Obtained...

Children with chronic cough should undergo, at a minimum, a chest radiograph and, if age appropriate, spirometry with or without methacholine challenge. Chest radiographs are readily available and quickly obtained and interpreted. In general, spirometry is reliably performed in children over 6 years of age and can be obtained with appropriate resources down to 3 years of age. In extraordinarily challenging cases, anesthesia protocols exist for younger children. There is no reason for otolaryngologists to defer spirometry to other specialists.

Much attention has been paid not only in the medical literature but also in the lay press to radiation risks associated with medical imaging. Parents often ask for clarification of these very real and historically underappreciated risks. Suffice is to say that the lifetime radiation-induced cancer risk is age and dose dependent. A single chest CT scan delivers about 5.8 mSv, which is the equivalent of that delivered with 300 plain chest radiographs that only deliver approximately 0.02 mSv. Depending on the algorithm, CT scans of the paranasal sinuses deliver less than that associated with chest CT scans. Although the initial driver to abbreviate sinus CT algorithms was cost effectiveness in comparison to the previous gold standard of four-view plain sinus series, the more meaningful advantage in retrospect relates to the lower radiation-related cancer risk.

High-resolution chest and sinus CT are the current gold standards for evaluating airway anatomy. Although much discussion has ensued over the relative value of alternative surrogates such as four-view plain sinus x-rays, ultrasound, and transillumination, such a discussion here would only speak to historical significance.

A purified protein derivative (i.e., PPD) may be valuable to rule out tuberculosis (TB) in immunocompetent patients. Remember that a PPD may not convert in immunocompromised patients who are most likely to contract the illness. Hemoptysis may suggest either malignancy or TB. Indirect laryngoscopy will often reveal blood-tinged secretions in the posterior commissure and on the mucosa of the true vocal cords in active TB. Induced sputum for gram stain, acid-fast stain, and culture may be useful.

Step Eight—If the Diagnosis Remains Elusive...

Airway endoscopy must be considered. For the otolaryngologist, an endoscopic survey begins in the nose. Although not included in the traditional "panendoscopy" sequence, nasal endoscopy has become a very important diagnostic tool in several clinical pediatric scenarios with none more compelling than chronic cough. By carefully evaluating the nose and nasopharynx, congenital anomalies such as pyriform aperture stenosis, choanal atresia, and septal deviations can be identified. The status of the nasal mucosa and secretions can be established. In cases of suspected infection due to resistant pathogens, directed middle meatal and nasopharyngeal cultures can serve the same role as tympanocentesis in middle ear disease. Lastly, the adenoid can be carefully assessed, which is particularly important since adenoidectomy is often the first and most common surgical procedure recommended for children with medically refractory sinonasal disease.

Bronchoscopy must be considered when there is a suspicion of a foreign body, an airway abnormality, focal and localized radiographic changes, and aspiration lung disease.

Similarly, esophagoscopy may assist in the diagnosis of esophageal anatomic anomalies, reflux or eosinophilic esophagitis, and food impaction. It is important to note that esophageal foreign bodies serve as an important and often overlooked cause of chronic cough. This factor underscores the importance of panendoscopy, which includes a careful survey of the esophagus in such cases.

Step Nine—Remember Once Again that Children with Cough are Not Simply Small Adults...

Hence, the adult literature cannot be blindly extrapolated to children. Although there are several reasons for this, the most important are as follows. First, viruses that only cause "common colds" in adults can cause serious respiratory illness in children. Second, there are distinct maturational differences in airway anatomy, respiratory musculature, and chest wall structure. Third, there are vastly different responses to medications. Fourth, medical history in very young children is limited by parental perception and availability. The conclusion, therefore, is obvious. Children should be managed according to pediatric studies and guidelines when available.

Step Ten—Remember this Important Pearl…

Children with chronic productive purulent cough should always be investigated for possible bronchiectasis and underlying treatable causes such as cystic fibrosis, primary ciliary dyskinesia, and immunodeficiency. It is the rule and not the exception that over the course of a career, a pediatric otolaryngologist will be the first to make one of these diagnoses.

Final Step—Don't Ignore the Absence of a Cough When there Should be One

It has often been said that crimes of commission are readily apparent. Crimes of omission are more challenging to identify. The practice of medicine is no different. Health care providers are more inclined to suspect pathology based on the *presence* of signs and symptoms. The astute clinician must also know when to be concerned by symptoms that are absent. There are several reasons why cough may be absent despite pathology normally associated with this symptom. The most common reason is loss of the cough receptor or the afferent limb of the reflex arc. It is for this reason that testing for an LAR has become a standard part of every swallowing assessment. The second reason that may either weaken or eliminate cough pertains to the mechanics of cough production. Specifically, the mechanics of a cough involve first developing and then sustaining a high velocity column of air. To do this, the cough begins with an initial inspiratory phase during which the vocal cords are maximally abducted and the chest dimensions increase; the lungs are filled with air to a high volume. Abnormalities that would compromise cough during this initial mechanical phase include restrictive or obstructive lung disease that prevents forceful inspiration, diaphragmatic weakness, or conditions that prevent vocal fold abduction such as paralysis and cricoarytenoid joint fixation. It is important to be mindful that a single flexible fiberoptic laryngoscopy may not be sufficient to rule out abnormal vocal fold mobility as certain etiologies such as Chiari malformation may present with intermittent paresis. The central pathology underlying the vocal fold immobility may not be diagnosed prior to the consultation. The otolaryngologist must consider brain, neck, and chest imaging in such cases where there is a reasonable index of suspicion. Generally, this index of suspicion arises during endoscopy where the inflammatory findings are out of proportion to what is generally a paucity of symptoms.

The second phase follows with rapid closure of the larynx at the supraglottic and glottic levels. Expiratory muscle contraction forces a rise in airway pressure during this compressive phase of coughing. It is the closure of the ventricular bands (false focal folds) that contributes the greatest sphincteric effect in preventing the flow of air during the compressive phase.

The third (expiratory) phase occurs as the glottis suddenly opens and rapid airflow expectorates mucus and foreign material. Maintenance of airflow velocity is assisted during expiration by continued narrowing of the opened supraglottic larynx. Vibrations of the laryngeal mucosa also assist in secretion clearance during the expiratory phase. Disorders affecting these latter two phases include those which weaken or prevent sphincteric laryngeal function (i.e., paralysis) and neuromuscular disorders that cause paresis. Finally, loss of sensitivity of the cough reflex is most commonly seen as a function of age. In children, it almost always suggests the presence of a very chronic pathologic process. This is most commonly seen in children with severe long-standing oromotor dysmotility who have aspirated for many years. Eventually, these patients only cough in response to extreme stimulation. If the clinical picture does not render the etiology of such a process obvious, an exhaustive search for such an explanation is imperative.

Etiologies of Cough

It is beyond the scope of this chapter to comprehensively detail the various etiologies of cough. What follows is a brief listing of diagnostic considerations with the exception of GERD, which is more completely discussed.

Sinonasal Causes of Cough

All such entities are covered elsewhere in this text in detail. A few points specific to cough, however, are warranted. First, although it is well documented that upper airway cough syndrome (i.e., "postnasal drip") is a common cause of cough in adults, no such data exist in children. In fact, to the contrary, a relationship between nasal secretions and cough is far more likely in children to be linked by a common infectious or inflammatory etiology. Second, abnormal sinus radiographs are found in between 18% and 82% of asymptomatic children. One of the biggest frustrations for otolaryngologists arises in children referred with abnormal sinus radiographs and cough whose parents have been prematurely and often erroneously set up to expect sinonasal disease as the definitive cause. It requires substantially more effort for the consultant to prove to parents that sinonasal disease is not the cause of cough than it does to prove that it is. Third, to date, there are no published prospective randomized controlled trials that assess the efficacy of medical therapies for upper respiratory tract disorders using nonspecific cough as the primary outcome measure.

Airway Lesions and Cough

Interestingly, the prevalence of airway lesions found in asymptomatic children is unknown, hence, their identification in children with chronic cough fails to definitively establish a cause-and-effect relationship. A relationship between an airway lesion and chronic cough can only be postulated. Tracheomalacia may impede airway secretion

clearance and also increases the risk of pneumonia distal to the malacia (33). Laryngomalacia is highly associated with reflux laryngopharyngitis.

Environmental Toxicants

A very sensitive issue to discuss with parents is the impact of passive smoke inhalation on their children. The data are irrefutable that passive smoke inhalation increases susceptibility to respiratory infections (34,35) and cough illnesses (36,37). Such relationships are especially true in children with asthma. In all children with chronic cough, exacerbating factors such as environmental toxicant exposure must be identified and interventional options for the cessation of the exposure be advised and initiated.

Chronic Nocturnal Cough

Traditionally, this pattern was said to immediately suggest two things. First, a chronic cough present only at night was thought to essentially eliminate rhinosinusitis as an etiology. Second, chronic nocturnal cough was said to be a direct indicator of asthma. In reality, neither of these precepts are absolute truisms. It is common that children with rhinosinusitis will experience a marked worsening of cough at night. The contrast is so striking that parents often only notice nighttime cough. Because parents are trying to sleep at night and the household is generally quiet, parental perception is often focused on nighttime cough even when rhinosinusitis is the cause. Regarding asthma, community-based studies reveal that only one-third of children with isolated chronic nocturnal cough have asthma. Surprisingly, no studies have objectively proven that nocturnal cough is worse than daytime cough in controlled asthmatics. In the end, these features are worth noting but in and of themselves do not constitute a basis for diagnosis.

Post-Infectious Cough

A cough that follows a viral URTI is referred to as a post-viral cough. The natural history has not been rigorously studied beyond 25 days. What further complicates the study of this etiology is the development of a new viral infection prior to complete recovery from the initial one. This is especially prevalent in younger children enrolled in daycare. At times simply identifying this etiology and presenting the self-perpetuating scenario to parents provides impetus to explore alternative child care that in and of itself may lead to resolution of the cough. It is also instructive to point out to parents that children under the age of 4 years average 5 to 8 distinct infections per year. Children 10 to 14 years of age average 2.5 to 5 infections per year (38). It is important to keep in mind that classic infections with cough as a primary symptom such as pertussis or "walking pneumonia" (i.e., *Mycoplasma*) generally present with symptoms in addition to cough. Confounding this basic tenant, however, is that antibiotics and vaccination must be considered as potential modifiers of the classical presentation and natural history.

Foreign Body

It is rare that acute onset of cough in the setting of a witnessed foreign body aspiration or choking episode is not evaluated endoscopically for the presence of an airway foreign body. Far more pernicious are cases of chronic cough, especially in younger children under 5 years of age, with onset not preceded by any such witnessed event. The otolaryngologist must always consider the possibility of an airway foreign body when presented with a child with chronic cough. Unfortunately, a normal plain radiograph of the chest does not exclude the diagnosis. Inspiratory and expiratory plain chest radiographs may increase the diagnostic yield as may an auscultatory examination with a double-headed stethoscope. In this author's opinion, facility with a double-headed stethoscope is the single most important part of the physical examination in such cases.

Gastroesophageal Reflux Disease—It's ok to Put the Cart Before the Horse

As stated earlier, chronic cough has more than 20 causes, and in up to 62% of cases, more than one cause is identified (18). Of these potential etiologies, reflux-related cough is the second most common cause of cough identified in 40% of this patient population. Interestingly, gastroesophageal reflux (GER)-related chronic cough is *defined as a cough that improves or is eliminated with GER-specific therapy*. It is rare in medicine to include in the diagnostic definition of an entity a mandatory concomitant response to treatment. As is true of most entities described in this section, not only can an entire chapter be easily dedicated to GER but as readily an entire book. Virtually every respiratory tract disorder including otitis media, sinusitis, laryngitis, laryngotracheal stenosis, recurrent pneumonia, and apnea has implicated some role for GERD.

So, specific to cough and in addition to the epidemiology just described, what are the salient issues? Unlike most diagnoses that are suggested over 80% of the time based on history and symptoms, GER is clinically silent in up to 75% of patients with GER-related chronic cough. This sets the stage for a very mixed blessing. On the one hand, it serves as a justification to not only consider but to also empirically diagnose and treat patients with chronic cough for GER. This often creates a vicious diagnostic web from which it is often very difficult to escape when GER does not apply. On the other hand, if one attempts to lessen the emphasis on GER, one risks overlooking a very obvious, common, and straightforward cause. In the ACCP published evidence-based guidelines for the diagnosis and management of chronic cough, initiating empiric GER therapy using lifestyle modification therapy and proton

pump inhibition in order to identify and treat GER-related chronic cough was recommended.

How long should empiric GER treatment be prescribed? The answer is not straightforward as cough often resolves within 2 weeks of proton pump inhibitor therapy though may take more than 50 days to respond in some patients. Most clinicians consider a 2-month empiric trial reasonable before pursuing more aggressive interventions. Clearly, the keys are to communicate to patients and their families that the diagnosis and treatment are empiric, meaning that GER may not play a role. One must also emphasize the variable timing of response. Finally, it is absolutely critical to have explored other serious causes of cough requiring more immediate treatment. Delaying treatment of a malignant tumor for 60 days is medicolegally unacceptable.

So, if one adheres to this guideline, in what instances should one consider diagnostic testing? At the most basic level, nonresponders should be considered for endoscopy, impedance monitoring, and/or dual esophageal pH-probe testing. From a treatment standpoint, medical nonresponders will have to be considered for fundoplication. Consider early consultation for fundoplication in patients suspected of having nonacid GER. Gastric outlet obstruction should be considered. Much of the confusion pertains to lack of a readily available diagnostic gold standard to make this diagnosis. Further complicating the diagnostic approach is confirming that, even if evidence for GER exists, it is also directly causing the symptom. Although many assume that one naturally leads to the other, such is not the case. In the end, proof that GERD causes chronic cough in children is rare. Infants often regurgitate, yet few well infants cough with these episodes. The prospective data available suggest that GERD is infrequently the sole cause of cough in children.

Etiology Specific Cough Treatment

In real estate, the hackneyed mantra is "location, location, location!" The authors suggest that for cough it should be "inflammation, inflammation, inflammation!" When considering etiology and most definitely when recommending treatment, invariably the final common denominator is most often inflammation. At times, the inflammation will spontaneously resolve upon identification, elimination, and treatment of the underlying cause of the inflammation. Such is the case for airway foreign body, GER, and atopy to some degree. At other times, the inflammatory mediators and mechanisms have become self-perpetuating and autoregulating. Various immune-mediated conditions serve as the prototype for this category of patients. In the latter instance, "breaking the inflammatory" cycle may restore physiologic homeostasis and "cure" the patient. In other such instances, the very best that can be achieved is "control" of the chronic inflammatory process. Still other conditions represent an amalgamation of the two. Reactive airway disease serves as such a condition as potentiators can be identified and treated. Many other patients, however, have no such clearly identifiable triggers. There is still much to be investigated and understood about the inflammatory pathways that define cough. This is arguably the most intense focus of contemporary research and defines the next major breakthrough and advance for these patients.

Nonspecific Cough Treatment

One of the most notable and controversial implications of the ACCP guidelines is that OTC expectorants and cough suppressants (i.e., cough syrups and drops) are usually a waste of money. Surprisingly, the new ACCP cough guidelines were the first to provide comprehensive, evidence-based recommendations for the diagnosis and management of cough in children. They included a particularly strong warning against the use of OTC cough and cold medications in children 14 years old and younger.

The effectiveness of these remedies is unproven in the pediatric age group and thus may place younger children unnecessarily at risk for medication side effects such as liver damage due to accidental overdose. Particularly concerning are reports that accidental ingestion in children younger than 5 years is common. The American Academy of pediatrics also recommends against the use of codeine or dextromethorphan for treating cough resulting from any cause. Fundamental to all of these recommendations is that in most cases, a cough that is unrelated to chronic lung conditions, environmental influences, or other specific factors will resolve spontaneously. If the reader is to permanently commit but one principal from this section to memory it should be this. *Cough in children should be treated based on etiology, and there is no evidence for using medications for the symptomatic relief of cough.*

If antitussives and other related medications are used, children must be evaluated after all medication had been discontinued if cough persists beyond a reasonable time frame. An evaluation of the time to response is important. As far as asthma treatments, there is no evidence to support use of β_2 agonists or anticholinergic agents in children with acute cough and no evidence of airway obstruction. Similarly, there are no randomized controlled trials evaluating the use of systemic steroids in children with acute cough. Low-dose inhaled corticosteroids have been proven effective in most cases of childhood asthma (39–41), hence, a trial of budesonide at a dose of 400 μg/d equivalent dose with another evaluation in 2 to 3 weeks is recommended.

Antibiotics, Antihistamines, Decongestants

Antibiotics are often empirically prescribed for children with chronic cough. Two randomized controlled trials examined the treatment of chronic cough with antibiotics. The first trial comprised a cohort wherein 23% of the children had cough for more than 30 days while the second with a mean duration of cough for 21 to 28 days. Significant improvement was noted in the antibiotic treatment arm

in both studies with nasopharyngeal colonization predominantly consisting of *Moraxella catarrhalis*. A Cochrane review concluded that a 10-day course of antibiotics reduces the duration of short- to medium-term cough. Conversely, for acute cough, antihistamine in combination with decongestant were no more effective than placebo. Neither diphenhydramine nor dextromethorphan were more effective than placebo in treating nocturnal cough in children. A meta-analysis concluded that neither antihistamines alone nor in combination effectively reduced symptoms of the common cold in children. No level-one evidence has been published evaluating the treatment of cough persisting for greater than 4 weeks in children.

Irrespective of diagnosis, environmental influences and parental expectations should be discussed and managed accordingly. The astute clinician understands that cough often impacts the quality of both the child's and the parents' lives. Explicitly defining parental expectations and fears will enhance the efficacy of the management of cough in children. This final point is where the science of medicine ends and the art of medicine begins. If a clinician does not purposefully explore parental fears, the clinician may miss that the parent is actually seeking consultation to alleviate a fear of the child choking and dying, Sudden Infant Death Syndrome (SIDS), progression into life-threatening status asthmaticus, and possible resultant permanent chest wall injury. By these parents' criteria, a successful consultation concludes no more than the exclusion of these fears. Not unlike most conditions, a lower likelihood to administer OTC medications and fewer doctor visits occur with more highly educated mothers (42).

CONCLUSION

Indeed, the quote by George Hebert which began this chapter affirmed that "…cough cannot be hid." So fortuitous is that fact since cough along with stridor and aspiration serve as important warnings of potentially life-threatening pathology. It is most fitting to end with Chevalier Jackson's description of aspiration in children that he termed "self-drownage." He explained that, "The accumulation may literally drown the patient in his own secretions. Infants cannot expectorate, and their cough reflex is exceedingly ineffective in raising secretion to the larynx. The cough reflex may be entirely absent in children. Age may be cited as one of the most frequent etiologic factors in the condition of self-drownage. Bronchoscopic aspiration is quite efficient, and can save any patient not affected with conditions that are fatal by other pathologic processes" (43). As this chapter has described, modern medicine has advanced a long way from the methods of Chevalier Jackson. Yet, at the same time, the fundamental principals of diagnosis and management have remained constant. Perhaps this is yet another example of the time-honored precept that "the more things change, the more they stay the same."

HIGHLIGHTS

- Cough, aspiration, and stridor, although clinically distinct entities, often coexist due to the anatomic and functional interrelatedness of the structural etiologies of each.
- The complex structure and function of the upper aerodigestive tract often adversely alter the delicate coordination between swallowing and respiration.
- Always suspect vascular anomalies in a child with "atypical asthma" or in children with severe symptoms associated with respiratory tract infections out of proportion to what is expected, especially when a history of noisy breathing since birth is elicited.
- Cricothyroidotomy is not recommended in pediatric patients due to the small size of the cricothyroid membrane and the increased incidence of laryngeal injury.
- Tracheostomy should be viewed as a temporizing measure until more definitive control of aspiration can be achieved and should be recommended judiciously.
- Chronic cough has more than 20 causes, and in up to 62% of cases more than one cause is identified from more than a half dozen distinct anatomic locations with receptors found in the nose, nasopharynx, posterior oropharynx, external auditory canals, tympanic membranes, stomach, esophagus, pleura, pericardium, and diaphragm.
- There are nearly 30 million physician visits for cough in the United States each year, positioning cough amongst the top five for number of doctor visits with nearly 3.5 billion dollars spent on OTC cough medications.
- In and of itself, cough does not represent a sign of disease. To the contrary, cough is an important normal protective reflex activity. The most widely recognized neural response involved in airway protection is cough.
- Cough in children should be treated based on etiology, and there is no evidence for using medications for the symptomatic relief of cough.

90 Laryngeal Stenosis

Michael J. Rutter *Aliza P. Cohen* *Alessandro de Alarcón*

Airway management of the infant, child, or adolescent may transform from the stable and routine to abrupt and life-threatening loss of the airway. This may occur either as a result of the underlying pathology or from the management of the pathology. Given the importance of a potentially emergent situation, the clinician must have a sound understanding of the causes, clinical presentations, and management of laryngotracheal stenosis. Our chapter therefore focuses on this content.

AGE-RELATED ANATOMIC DIFFERENCES IN THE LARYNX

Although the three portions of the larynx (supraglottis, glottis, and subglottis) are the same in children and adults, there are a number of age-related differences that play a role in the development of laryngotracheal stenosis.

Laryngeal Size

The infant larynx is approximately one-third the size of the adult larynx; however, it is proportionally larger than the adult larynx relative to the rest of the tracheobronchial tree. The infant vocal fold also differs in length from the adult vocal fold; it is approximately 7 to 8 mm long, whereas the adult vocal fold is 14 to 23 mm long. In the infant, half of the length of the true vocal fold is composed of the vocal process of the arytenoid. In the adult, the vocal process occupies only one-fourth to one-third of the total length of the true vocal fold. The subglottis is the narrowest part of the airway because of the complete ring structure of the cricoid cartilage. In the infant, the subglottis is approximately 4.5 to 7 mm in diameter. A child with a subglottic diameter of 4.0 mm or less has subglottic stenosis (1).

Laryngeal Location

The position of the larynx in relation to other structures of the neck is different in infants and adults. In the infant, the superior border of the larynx is located as high as the first cervical vertebra, with the cricoid cartilage positioned at approximately the level of the fourth cervical vertebra. This results in the hyoid overriding the superior larynx in an infant, with the thyroid notch usually being impalpable as a consequence. Because of the superior positioning of the larynx, the epiglottis approximates the dorsal surface of the soft palate. This contributes to the obligate nasal breathing seen in the first months of life. As the child grows into adulthood, the larynx gradually descends, and the cricoid cartilage eventually rests at the level of the sixth cervical vertebra. The infant epiglottis is the structure that demonstrates the most dramatic change in configuration. At birth, the epiglottis, which is shaped like the Greek letter omega (Ω), is narrower and softer than the epiglottis in older children and adults. It has a less stable base, and there is a more acute angle between the epiglottis and glottis, allowing the epiglottis to fall into the laryngeal inlet. As the child grows, cartilaginous support of the epiglottis becomes more rigid, and the angle of the thyroid cartilage changes from 110 to 120 degrees to an angle of 90 degrees in the adolescent male. In the adult female, this angulation remains more obtuse, as in childhood. Because cartilage, muscle, and submucosal tissues are more pliable and less fibrous in the infant than in the adult and because the airway is so narrow at the subglottis, any process that produces edema can cause significant airway obstruction. Circumferential mucosal edema of 1 mm within the larynx of an infant narrows the subglottic space by more than 60% (2). Within the fixed ring of the cricoid cartilage, edema will cause a marked diminution in potential

airflow. This diminution is best explained by Poiseuille's Law, which relates resistance to airflow (Q) across an area of narrowing to the inverse of the radius of the lumen to the fourth power ($Q \approx 1/r^4$). Thus, 1 mm of edema in an infant results in a 75% decrease in luminal diameter and a 16-fold increase in resistance through the airway. This same degree of narrowing in the adult reduces the diameter of the airway by only 30% and doubles airway resistance.

LARYNGEAL STENOSIS

Laryngeal stenosis may occur in the supraglottis, glottis, or subglottis. Clinically, subglottic stenosis is by far the most common problem requiring intervention, followed by glottic stenosis. Supraglottic stenosis is rare in children and is usually a consequence of thermal or chemical injury or iatrogenic injury following previous airway reconstructive surgery. Evaluation of congenital stenosis of the larynx can often be determined by the signs and symptoms of obstruction, which differ depending on the specific anatomic level of laryngeal narrowing. These signs and symptoms help the clinician in the initial assessment of the patient (Table 90.1).

Subglottic laryngeal obstruction produces a hoarse and husky voice with pathognomonic biphasic stridor. Patients may also have a barking cough. Feeding is normal unless there is a severe airway obstruction.

Signs and symptoms of glottic obstruction include a hoarse, aphonic voice with inspiratory stridor that may become biphasic as the severity of the obstruction increases. As in patients with subglottic obstruction, feeding is normal unless the airway obstruction is severe. Patients usually have no cough. Patients with posterior glottic stenosis usually present with a normal voice, and may mimic bilateral vocal fold paralysis in this regard.

Supraglottic laryngeal obstruction produces a muffled or throaty voice with an inspiratory fluttering stridor. Patients may present with significant feeding problems but no cough. The airways of children with supraglottic stenosis are among the most challenging airways to manage, as the stenosis is often further complicated by dynamic supraglottic collapse. An individualized approach is essential in these patients.

TABLE 90.1 SIGNS AND SYMPTOMS OF LARYNGEAL STENOSIS

Laryngeal Region	Signs and Symptoms
Subglottis	Hoarse or normal voice, biphasic stridor, normal feeding (except with severe obstruction), barking cough
Glottis	Hoarse voice or aphonia, inspiratory (early) or biphasic (late) stridor, normal feeding (with or without severe obstruction), no cough
Supraglottis	Muffled voice, fluttering inspiratory stridor, severe feeding problems, no cough

Congenital Laryngeal Stenosis

Subglottic Stenosis

Subglottic stenosis in the neonate is defined as a lumen 4.0 mm in diameter or less at the level of the cricoid. A relevant reference point is the outer diameter of an endotracheal tube. For example, a 2.5 endotracheal tube has an outer diameter of 3.6 mm, and a 3.0 endotracheal tube has an outer diameter of 4.2 mm.

It is important to differentiate congenital from acquired subglottic stenosis. Acquired subglottic stenosis is caused by intubation or other forms of laryngeal trauma; this is often an iatrogenic injury caused by a complication of medical therapy. Acquired subglottic stenosis is generally more severe, requiring aggressive, long-term management (discussed later in this chapter). In the absence of trauma, an abnormality of the cartilage or subglottic tissues is usually considered to be congenital. The cause of congenital subglottic stenosis is thought to be a failure of the laryngeal lumen to recanalize (3). This abnormality lies on a continuum of embryologic failures that includes laryngeal atresia, stenosis, and webs. In its mildest form, congenital subglottic stenosis manifests with a normal-appearing cricoid with a smaller-than-average diameter, usually with an elliptical shape.

A mild case of subglottic stenosis may produce a clinical picture of recurrent upper respiratory infections, often diagnosed as croup, in which minimal subglottic swelling precipitates airway obstruction. The greatest obstruction is usually 2 to 3 mm below the true vocal folds in a young child.

More severe cases of congenital subglottic stenosis may present with acute compromise of the airway at delivery. If endotracheal intubation is successful, the patient may require intervention before extubation. In more severe cases, when intubation cannot be achieved, a tracheotomy may be lifesaving at the time of delivery. Interestingly, however, infants with congenital subglottic stenosis may have surprisingly few symptoms, and even children with grade III subglottic stenosis may not present for weeks or months.

Congenital subglottic stenosis is often associated with other congenital head and neck lesions and syndromes (e.g., a small larynx in Down syndrome). After the initial management of congenital subglottic stenosis, the larynx will grow with the patient and may not require further surgical intervention.

Congenital subglottic stenosis can be divided histopathologically into membranous and cartilaginous types (1,2) (Table 90.2). The membranous type is usually

TABLE 90.2 HISTOPATHOLOGIC CLASSIFICATION OF SUBGLOTTIC STENOSIS

Membranous stenosis
- Granulation tissue
- Submucosal gland hyperplasia
- Submucosal fibrosis

Cartilaginous stenosis
- Cricoid cartilage deformity
  - Normal shape that is small for infant's size
  - Abnormal shape
    - Large anterior lamina
    - Large posterior lamina
    - Generalized thickening
    - Elliptical shape
    - Submucosal cleft
    - Other congenital cricoid stenosis
- Trapped first tracheal ring

Combined stenosis

TABLE 90.3 GRADING SCALE FOR LARYNGEAL STENOSIS

Grade	Laryngeal Lumen Obstruction
I	<50%
II	51%–70%
III	71%–99%
IV	Complete obstruction

circumferential and presents as a fibrous soft tissue thickening in the subglottis caused by increased fibrous connective tissue or hyperplastic mucous glands. It usually includes the area 2 to 3 mm below the true vocal folds, but it may extend upward to include the true cords. The cartilaginous type commonly presents as a thickening or deformity of the cricoid cartilage that creates a shelf-like plate of cartilage on the inner surface of the cricoid ring, extending posteriorly as a solid sheet and leaving only a small posterior opening (1). Stenosis may also be caused by a trapped first tracheal ring.

Although the histopathologic picture may vary, the diagnosis of subglottic stenosis is based on endoscopic assessment. The stenosis due to a scar, granulation tissue, submucosal thickening, or a congenitally abnormal cricoid can be differentiated from subglottic stenosis with a normal cricoid, but endoscopic measurement with endotracheal tubes or bronchoscopes is required for an accurate evaluation. Many laryngeal stenoses represent a combination of a congenitally small larynx further traumatized by endolaryngeal intubation or instrumentation.

Radiographic evaluation of a patient's unintubated airway may give the clinician clues about the site and length of the stenosis. Useful imaging modalities include inspiratory and expiratory lateral soft tissue neck films; fluoroscopy to demonstrate the dynamics of the trachea and larynx; and a chest radiograph. The single most important investigation, however, remains high-kilovoltage airway films. These films are helpful in identifying the classic steepling seen with subglottic stenosis and also in providing a warning of tracheal stenosis; this is usually caused by complete tracheal rings, which may place the child in a life-threatening situation during rigid endoscopy.

Endoscopy is necessary for the diagnosis of laryngeal stenosis. Flexible fiberoptic endoscopy provides information on dynamic vocal fold function. Rigid endoscopy with Hopkins rod lens telescopes provides the best possible examination. Precise measurement of the endolarynx and staging of the laryngeal stenosis can be carried out. The most commonly used system for staging subglottic stenosis is the Myer-Cotton grading scale (Table 90.3). Most grade I and many grade II lesions do not require surgical intervention; however, grade III and grade IV lesions generally necessitate a surgical approach.

Laryngeal Webs

Supraglottic webs represent fewer than 2% of congenital laryngeal webs (Fig. 90.1). These webs are diaphragmatic outgrowths that usually arise anteriorly. If partial, they provide air passage posteriorly. The web is typically thickened anteriorly and thins out toward the posterior edge. Symptoms, including dyspnea and voice change, depend on the size and position of the web. Ten percent of children with supraglottic webs have associated congenital anomalies.

More than 90% of laryngeal webs are anterior glottic webs, representing a failure to completely recanalize the larynx. Patients usually present with an abnormal cry or respiratory distress at birth. Virtually all glottic webs are anterior, with varying degrees of compromise of the glottic airway. Although some webs are gossamer thin, most anterior glottic webs are thick and usually associated with a subglottic "sail" compromising the subglottic lumen. As such, they may be considered a form of partial laryngeal atresia. Thin webs may escape detection because neonatal intubation for airway distress may lyse the web. Thick webs require open reconstruction with either reconstruction of the anterior commissure or placement of a laryngeal keel. Approximately 40% of patients with thick membranous webs require tracheotomy placement. There is a strong association between anterior glottic webs and velocardiofacial syndrome (4).

A web can also form in the subglottic region, mimicking cricoid cartilage deformities or subglottic stenosis. Subglottic webs account for approximately 7% of laryngeal webs and are anteriorly based, with a small posterior

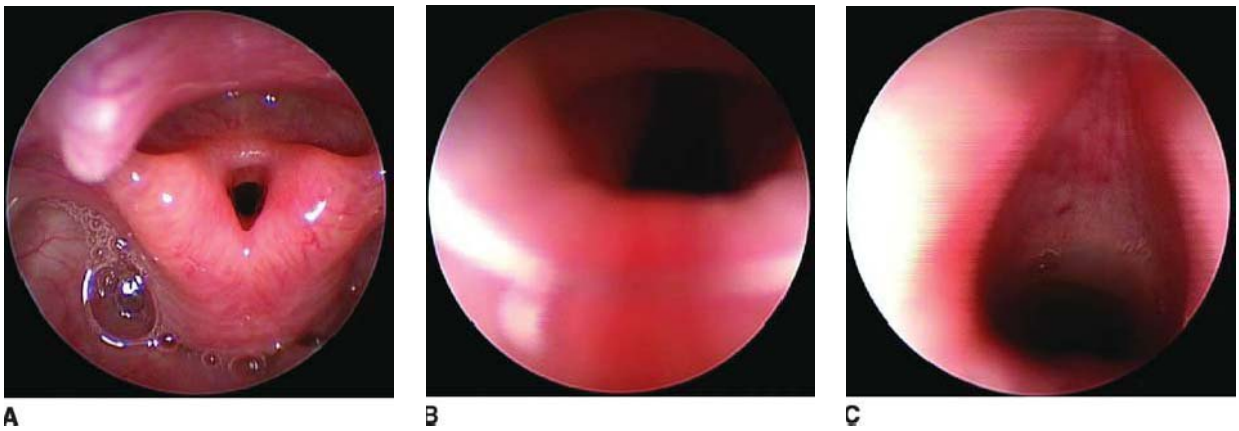

Figure 90.1 Endoscopic view of a patient with a congenital supraglottic web **A**: 0-degree telescope. **B**: 30-degree telescopic view. **C**: 30-degree telescopic view showing normal vocal folds beyond the web.

opening that may be only the size of a pinpoint. The superior surface is covered with squamous epithelium, and the inferior surface is mucous membrane. A slight female predominance has been reported. Symptoms include aphonia, respiratory distress, and biphasic stridor. The diagnosis must be made by flexible fiberoptic or rigid endoscopy.

Atresia

Laryngeal atresia (supraglottic, glottic, subglottic) represents complete failure of the lumen of the larynx to recanalize, and is therefore the most severe form of laryngeal stenosis. This condition is associated with a high frequency of other congenital anomalies, including esophageal atresia, tracheoesophageal fistula (TEF), urinary tract anomalies, and limb defects, particularly those that involve the radius. If a TEF exists, ventilation may occur through this communication. Tracheotomy is essential if the patient is to survive. Many children are not properly diagnosed in time for the appropriate intervention, and the diagnosis may be made postmortem. In the absence of a TEF, the lungs and major airways expand due to the pressure of fluid secreted by the lungs, leading to eversion of the diaphragms, development of a prune belly, and fetal hydrops; this constellation is known as congenital high airway obstructive syndrome.

Complete laryngeal atresia is challenging to repair due to the associated small cricoid. Reconstruction involves anterior cricoid resection, posterior cricoid expansion, web division, and prolonged stenting. This is usually best left until the child is older than 4 years of age. It is unlikely that a single operation will achieve decannulation.

Acquired Laryngeal Stenosis

Postintubation Stenosis

In 1965, McDonald and Stocks (5) advocated long-term nasotracheal intubation in the management of the unstable neonatal airway. Although this revolutionized neonatal care, especially for the premature infant, there was a corresponding increase in the incidence of acquired subglottic stenosis in neonates with prolonged stays in neonatal intensive care units. The incidence of combined congenital and acquired subglottic stenosis also rose as infants with congenital subglottic stenosis were intubated for airway compromise, often with inappropriately large endotracheal tubes. Acquired subglottic stenosis resulting from prolonged neonatal intubation is now more common than congenital stenosis in the pediatric age group.

The pathogenesis of acquired subglottic stenosis is still not understood, although several theories have been proposed. Autopsy studies demonstrate that there is a period of ulceration and necrosis of cricoid mucosa in the first hours and days of intubation (5). Quiney and Gould (6) reported healing and reepithelialization in the cricoid region, even while the endotracheal tube remained in place. However, 1% to 8% of neonates develop stenosis after prolonged intubation (7). The incidence has steadily dropped over the last three decades despite the longer periods of intubation that have become commonplace in increasingly smaller infants. Although several factors are involved, the two most significant factors have been the abandoning of red rubber endotracheal tubes and the realization that the ideal endotracheal tube size is not the largest that will fit but rather the smallest that can permit adequate ventilation. Ideally, an endotracheal tube should leak air around it with subglottic pressures below 20 to 25 cm of water.

Flexible fiberoptic laryngoscopy should be a routine part of the initial evaluation of the larynx. Vocal fold paralysis may prohibit decannulation, even after successful surgical reconstruction of a compromised airway. Rigid endoscopy using Hopkins telescopes is necessary for diagnosis and photo documentation. Correct sizing of the airway should be accomplished with appropriate-sized endotracheal tubes or rigid bronchoscopes. Radiographic assessment can provide information about the site and length of the stenosis that will assist in management decisions. In patients

with acquired stenosis, a prolonged period of observation after tracheotomy is inappropriate because of the high risk of death should the tracheotomy tube become obstructed. Therefore, surgical reconstruction is often undertaken to create a safer airway.

Post-Tracheotomy Stenosis

During a tracheotomy, additional injury may result in laryngotracheal stenosis or suprastomal collapse. Secondary infection, chondritis, or pressure exerted by the curvature of the tracheotomy may result in stenosis or suprastomal collapse above the tracheotomy site. Stenosis may occur because of a high tracheotomy, which is performed through the thyroid, cricoid, or first tracheal cartilage; a high tracheotomy also includes cricothyroidotomy. Although this procedure is well known to otolaryngologists and emergency room physicians as a lifesaving intervention, it may result in a complication rate as high as 32% (8).

Post-Reconstruction Restenosis

Subglottic stenosis may also result after failed laryngotracheoplasty. This is more likely to occur if the original procedure was not aggressive enough or there is concomitant bacterial infection, development of granulation tissue, malalignment or improper stent sizing, or histopathologic changes. Indeed, any form of airway surgery, endoscopic or open, has an attendant risk of resultant airway restenosis. There is greater risk of restenosis following airway reconstruction if the larynx is actively inflamed. This is most commonly seen in patients with gastroesophageal reflux disease (GERD), but may also be seen in patients with eosinophilic esophagitis (EE). Optimally, both of these conditions should be treated before reconstructive surgery is performed. Occasionally, an active larynx is seen in a patient who does not have either GERD or EE. In this setting, spontaneous resolution with time is expected, and patience prior to airway surgery is recommended.

Infectious or Inflammatory Stenosis

Laryngeal stenosis caused by infectious or inflammatory disorders is usually the result of end-stage processes of untreated disorders.

Granulomatous Disease

Tuberculosis of the larynx is the most common granulomatous disease of the larynx, and it is usually associated with pulmonary disease. The most common sites for laryngeal tuberculosis are the interarytenoid space, arytenoid cartilages, posterior surface of the true vocal folds, and laryngeal surface of the epiglottis. The patient may present in the early stages of disease with diffuse edema and erythema of the cords, which may mimic an early-stage glottic carcinoma. However, disease progression manifests with nodular lesions and ulceration of the epithelium, which can lead to perichondritis and chondritis. Due to interarytenoid muscular involvement or cricoarytenoid joint fixation, patients may also present with symptoms that mimic vocal fold paralysis. Diagnosis is made by demonstration of *Mycobacterium tuberculosis*. Successful treatment usually leads to complete healing of the larynx. If the disease is not treated, chondritis and necrosis will destroy the larynx with extensive scarring and stenosis.

Sarcoidosis, rhinoscleroma, and Wegener granulomatosis are all rare disorders in children. Wegener granulomatosis may respond well to steroids, cyclophosphamide, and possibly, co-trimoxazole. It has a predilection for the subglottis and, once quiescent, may require airway reconstruction with cricotracheal resection being more efficacious than standard laryngotracheal reconstruction utilizing expansion cartilage grafting techniques.

Trauma

Because laryngeal trauma is discussed in Chapter 77, our comments here are brief. If trauma is mismanaged or unrecognized, it may lead to laryngeal stenosis. Sources of internal trauma include foreign bodies and instrumentation during endoscopic procedures. These forms of trauma usually lead to glottic and subglottic scarring and resultant stenosis. External forms of laryngeal trauma, such as motor vehicle accidents, sports-related injuries, and assaults, including blunt and penetrating trauma, can also produce laryngotracheal stenosis.

Anterior blunt trauma, as sustained in motor vehicle accidents or sports-related injuries, usually leads to posterior supraglottic and glottic stenosis. An external force at the hypopharyngeal level may cause scar formation between the epiglottis and posterior pharyngeal wall. Fracture of the hyoid bone displaces soft tissues posteriorly, narrowing the laryngeal inlet. These injuries may also cause web formation on the posterior hypopharyngeal wall and stenosis in the postcricoid area. Blunt and penetrating trauma may lead to laceration or hematoma formation in the glottis, which will produce laryngeal stenosis if not treated appropriately.

Systemic Diseases

Laryngeal stenosis due to fixation of the cricoarytenoid joint may be caused by rheumatoid arthritis or juvenile rheumatoid arthritis (Still disease). About 25% of patients with rheumatoid arthritis present with limitation of the motion of the cricoarytenoid joint. Systemic lupus erythematosus and gout may also cause arthritis of this joint, leading to narrowing of the laryngeal inlet. Hoarseness, stridor, dyspnea, and pain are the signs and symptoms of arthritic involvement. Erythematous edema of the arytenoid with the vocal fold fixed in the paramedian or intermediate position may be found during examination. Diagnosis must include direct laryngoscopy with palpation of the arytenoid to differentiate this from vocal fold paralysis. Appropriate laboratory studies

include erythrocyte sedimentation rate, C-reactive protein, antinuclear antibodies, and rheumatoid factor.

Thermal Injuries

Thermal injuries of the glottis and subglottis may occur without thermal injury to the trachea and lung due to the cooling of air by the upper airway and reflex closure of the cords. Thermal injuries from steam, possessing 4,000 times the heat-carrying capacity of heated air or gas, may cause significant laryngeal burns. Laser airway fires may be particularly damaging. The pathophysiology of stenosis in laryngeal thermal injuries is thought to be governed by three factors: direct thermal injury, toxic effects of combustion products, and prolonged intubation. Once the scar tissue has matured, airway reconstruction may be successfully undertaken (9).

Caustic Ingestions

The results of caustic ingestions on oropharyngeal and esophageal mucosa are extensively reviewed in the literature, and indicate that laryngeal stenosis is rare. Both acidic and alkaline ingestions may cause supraglottic edema and airway obstruction, thus necessitating tracheotomy placement (10). Severe caustic ingestions may lead to fibrosis of the posterior cricoarytenoid muscle. Hypopharyngeal and supraglottic mucosal injury may cause supraglottic scarring and stenosis.

GERD and EE

GERD has long been thought to be an exacerbating factor in subglottic stenosis. GERD is common in children and disproportionately prevalent in children with subglottic stenosis. Although the appearance of the larynx and subglottis may strongly suggest GERD, there is no single definitive test to establish the presence of reflux that reaches the larynx. Gross reflux may occur with no obvious clinical signs on endoscopy. The clinician should therefore weigh the results of rigid laryngoscopy, esophagogastroduodenoscopy, esophageal biopsy, and dual pH probe or impedance probe tests in determining the role of GERD in each patient. In severe cases, GERD should be treated with H_2 blockers and proton pump inhibitors or fundoplication prior to reconstructive surgery.

EE is an uncommon disorder that, if untreated, may have a significant effect on the aerodigestive tract. Although many children with EE also have esophageal, laryngotracheal, and sinonasal complaints, many are asymptomatic (11). The diagnosis is made by histologic examination of biopsies taken from the esophagus at the time of esophageal endoscopy. In patients with active EE, the laryngotracheal complex is often inflamed. In this setting, surgery frequently elicits a brisk inflammatory response that can lead to graft failure or restenosis. If EE is present, our experience indicates that medical management followed by repeat endoscopy with biopsies is prudent. Once biopsies reveal that there is no active EE, surgery may be performed.

Radiation Effects

The effects of radiation on the adult pharynx and larynx are well established, particularly in the context of management of laryngeal malignancy (12). Although radiation therapy in curative doses in children is rarely required, the consequences may be similar to or worse than those seen in adults. Pharyngeal or laryngeal edema and stenosis may result, often with associated aspiration. Reconstructive surgery in these children is fraught with problems.

TRACHEAL STENOSIS

As with laryngeal stenosis, tracheal stenosis may be either congenital or acquired. Acquired stenosis is often secondary to trauma caused by intubation. The most commonly encountered congenital condition is complete tracheal rings. Although rare, this anomaly is life threatening. It presents with progressive worsening of respiratory function over the first few months of life, stridor, retractions, and marked exacerbation of symptoms during intercurrent upper respiratory tract infections. Children with tracheal stenosis generally exhibit a biphasic wet-sounding breathing pattern referred to as "washing machine breathing." This pattern transiently clears with coughing. The risk of respiratory failure increases with age in congenital tracheal stenosis, as the infant typically grows faster than the stenosis. Decompensation may occur around 4 months of age and is often incited by an upper respiratory tract infection.

An initial high-kilovolt airway radiograph may reveal tracheal narrowing; however, the diagnosis is established with rigid bronchoscopy. This must be performed with utmost caution, using the smallest possible telescopes, as any airway edema in the region of the stenosis may transform a narrow airway into an extremely critical airway. If the stenosis is severe, the stenotic airway should not be instrumented, even with the smallest telescope. The initial bronchoscopic view is often sufficient to establish the diagnosis, thereby avoiding the risk of airway edema. Because 50% of children have a tracheal inner diameter of approximately 2 mm at the time of diagnosis, the standard interventions for managing a compromised airway are not applicable. The smallest endotracheal tube has an outer diameter of 2.9 mm, and the smallest tracheotomy tube has an outer diameter of 3.9 mm. The stenotic segment can therefore not be intubated. This may leave extracorporeal membrane oxygenation (ECMO) as the only viable alternative for stabilizing the child. This circumstance is best avoided by performing bronchoscopy with the highest level of care. Over 80% of children with complete tracheal rings have other congenital anomalies, which are usually cardiovascular in origin. In view of this, investigations should include a contrast-enhanced chest high-resolution CT scan and an echocardiogram. Given that a pulmonary artery sling is a common association, it should be ruled out. If present, it should be repaired at the time of the tracheal repair. Most children with complete tracheal rings require tracheal reconstruction (13).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of laryngeal stenosis in children and adults must include all conditions that may cause stridor, dyspnea, and respiratory distress. For patients who do not present with acute respiratory distress, careful history taking can help the clinician localize the site of pathology. Because the presentation of laryngeal stenosis may vary from asymptomatic congenital subglottic stenosis in the infant to acute airway obstruction with supraglottic injury in the adult, the differential diagnosis is quite extensive. Table 90.4 outlines the major causes of stridor and respiratory distress that should be considered in the differential diagnosis of laryngeal stenosis in children and adults. Endoscopic examination with or without a biopsy provides the best chance for definitive diagnosis.

MANAGEMENT

Natural History

Severe congenital laryngeal stenosis requires immediate airway intervention, but fewer than half of patients with congenital laryngeal stenosis require tracheotomy. These patients may present only after repeated episodes of childhood laryngotracheal infections or later with exercise intolerance. Patients with acquired laryngeal stenosis produced by internal or external trauma, infectious processes, or iatrogenic causes are more likely to require surgical reconstruction or a tracheotomy because of more severe stenosis.

TABLE 90.4 COMMON CONDITIONS THAT MIMIC LARYNGEAL STENOSIS

Neonate
- Laryngomalacia
- Vascular compression (e.g., innominate artery, aberrant subclavian artery, vascular ring)
- Vocal fold paralysis
  - Bilateral (e.g., Chiari deformity)
  - Unilateral (e.g., traumatic post ductus ligation)
- Hemangioma, subglottic
- Complete tracheal rings
- Laryngeal cleft
- Cri du chat syndrome
- Laryngeal saccules, laryngoceles

Child
- Dermoid, saccular, epiglottic cysts
- Lingual thyroid
- Infections (e.g., epiglottitis, croup, bacterial, laryngotracheitis)
- Foreign body
- Papillomatosis

Adult
- Vocal fold paralysis (status post thyroid surgery, laryngeal carcinoma)
- Viral, granulomatous, fungal laryngitis
- Reinke edema
- Laryngeal trauma (blunt or penetrating)
- Postintubation
- Hemangioma, supraglottic
- Idiopathic (e.g., spastic dysphonia)
- Neurologic (e.g., amyotrophic lateral sclerosis, multiple sclerosis)
- Caustic ingestion
- Systemic disease (e.g., rheumatoid arthritis, polychondritis)
- Tracheal tumors or obstruction

Medical Therapy

Treatment of laryngeal stenosis must include prevention. In children, this consists of precise airway management, particularly of patients who require prolonged intubation. In children requiring prolonged intubation, management of sedation or paralysis by experienced personnel, and selection of an appropriate size of endotracheal tube, may all influence the laryngeal outcome. In adults, careful management of mucosal injuries after trauma or surgical resection reduces the chance of acquired laryngeal stenosis. Efficient and appropriate management of infectious or inflammatory disorders, thermal or chemical injury, and gastroesophageal reflux can diminish the chance of iatrogenic stenosis. Medical treatment often consists of supportive therapy, including humidification, antibiotics, or steroid therapy in a monitored and closely supervised setting if temporary airway compromise is anticipated. Management of GERD or EE may occasionally lessen the degree of subglottic stenosis without having to resort to surgery. Similarly, treatment of the underlying disorder in autoimmune subglottic stenosis may allow nonsurgical resolution of the disease.

Preoperative Assessment

If laryngeal stenosis is of a magnitude to warrant surgical reconstruction, the potential outcome of surgery should be optimized. GERD should be treated with proton pump inhibitors and H_2 blockers. Antireflux medication should be continued for 3 months postoperatively. Treatment of EE with either an elimination diet or with swallowed fluticasone will improve the surgical outcome.

An adequate pulmonology workup is required in many children, especially those with a history of bronchopulmonary dysplasia and an oxygen requirement. Removal of a tracheotomy tube in a patient requiring over 1 L/min of oxygen is not recommended.

If there is a suspicion of ongoing aspiration, if surgery will involve the glottis, or if surgery will repair a stenosis that may be preventing aspiration, it is prudent to have the patient undergo a swallowing assessment comprising both a videofluoroscopic swallow study and a fiberoptic endoscopic evaluation of swallowing (FEES). These complementary studies can evaluate the ongoing aspiration with swallowing as well as the likelihood of future aspiration (14,15). FEES offers the advantages of allowing visualization of laryngeal protective mechanisms, documentation of vocal fold motion, and assessment of the potential risk of aspiration prior to reconstructive surgery. Information

obtained from these assessments is crucial in planning the operative procedure and in counseling the family about the potential risk of aspiration.

For children who have a tracheotomy, aspiration in general as well as specific causes of aspiration can be assessed by conducting a dye test with green food coloring. Aspiration is suspected if stained secretions or feeds are noted from the tracheotomy during feeding or at any time after feeding. This test has no value in the evaluation of aspiration in children with a grade IV stenosis.

Because many airway reconstructive procedures involve a compromise between voice quality and airway improvement, preoperative voice evaluation has become increasingly important (16–18). For further discussion of this evaluation, refer to Chapter 91.

In light of the prevalence (30%) of colonization by methicillin-resistant *Staphylococcus aureus* and *Pseudomonas aeruginosa* in our patients with complex aerodigestive problems, we routinely screen for these bacteria by culturing of the nares and tracheal aspirate, both of which have a propensity for infecting cartilage and can lead to operative failure. Patients who test positive are treated with perioperative and postoperative antimicrobial therapy (19).

Endoscopic Evaluation

Endoscopic and surgical management are based upon two key principles: safely securing the airway and establishing a diagnosis based on endoscopic findings. Performing microlaryngoscopy and rigid bronchoscopy allows clinicians to identify anatomic levels of airway obstruction from the larynx to the carina. The supraglottis and glottis are assessed for stenosis, and the glottis is then evaluated for posterior glottic stenosis, anterior glottic web, and laryngeal cleft. If vocal fold immobility is suspected or seen on the FEES or voice evaluation, the cricoarytenoid joints should be palpated to determine if there is any fixation of the joint.

Rigid bronchoscopy is performed using Hopkins rod telescopes and rigid bronchoscopes. The subglottis is first evaluated. If subglottic stenosis is present, it is classified by the Myer-Cotton scale and sized using appropriate endotracheal tubes. The length of stenosis as well as its proximity to the vocal folds is also assessed and documented. If a tracheotomy is in place, attention is paid to the evaluation of the suprastomal area, considering the possibility of suprastomal collapse, granuloma, intratracheal skin tract, and high tracheotomy. The trachea is evaluated to the level of the carina, looking for additional pathology, including tracheal stenosis, complete tracheal rings, TEF, TEF pouches, vascular compression, and tracheomalacia.

Endoscopic and Surgical Management

Endoscopic management of laryngeal stenosis is successful in most cases involving grade I or II stenosis when there are no factors that predispose to failure (Table 90.5), whereas grade III and grade IV stenoses are more likely to require an open surgical approach. Endoscopic techniques include dilatation and scar division.

TABLE 90.5 FACTORS PREDISPOSING TO FAILURE IN TREATING SUBGLOTTIC STENOSIS WITH A CO_2 LASER

Failure of previous endoscopic procedures
Significant loss of cartilaginous framework
Combined laryngotracheal stenosis
Circumferential cicatricial scarring
Fibrotic scar tissue in the interarytenoid area of the posterior commissure
Abundant scar tissue >1 cm in vertical dimension
Severe bacterial infection of trachea after tracheotomy
Exposure of perichondrium or cartilage during CO_2 laser excision predisposing to perichondritis and chondritis
Concomitant tracheal disease

Endoscopic laser management of laryngeal stenosis has yielded success rates ranging from 66% to 80% (20). Careful patient selection is necessary for successful treatment. The advantages of successful endoscopic management include precise surgical excision, low surgical morbidity, minimal damage to underlying or surrounding tissues, and the ability to vary the amount of energy delivered. Endoscopic management of laryngeal stenosis potentially allows a successful outcome without a tracheotomy. Endoscopic laser techniques that use high energy over prolonged periods and damage underlying cartilage may create or worsen stenosis. Because of bacterial colonization of the aerodigestive tract, prophylactic antibiotic therapy is recommended.

Balloon dilatation of the airway using high-pressure noncompliant balloons has become a valuable addition to the tools used to manage airway stenosis. The best candidates for balloon dilatation are stenoses involving either thin or web-like scars, or relatively fresh stenoses. Repeated dilatation, at 1 to 3 week intervals, on up to four occasions may provide the optimal outcome. Adjunctive interventions, such as scar division (whether with a sickle knife or a laser) and steroid injection may further enhance the outcome of balloon dilation. Selection of balloon size is based upon the expected size of the normal airway—for example, a 4 year old should be intubated with a 5.0-mm endotracheal tube, with an outer diameter of nearly 7 mm. Therefore, the balloon size selected would be 7 to 8 mm for the larynx and 8 to 9 mm for the trachea.

If endoscopic management is unsuccessful or there are factors predisposing to endoscopic failure, a wide variety of open surgical techniques are available for managing laryngeal stenosis. This is generally the case in the setting of severe advanced acquired stenoses. Endoscopic diagnosis is imperative in selecting the appropriate surgical technique. The status of vocal fold mobility, the involvement of the posterior commissure, and a complete evaluation of the upper and lower airway are essential to the assessment.

The goal of open surgery for correcting laryngotracheal stenosis is to optimize voice function and permit early decannulation. Relative contraindications to open reconstructive surgery include (a) a significant risk in administering a general anesthetic, (b) the continued need for tracheotomy, and (c) significant laryngeal inflammation (GERD,EE) (21).

Open surgical management of the stenotic airway has evolved from Rethi's (22) original description of cricoid expansion in adults, which required a vertical cricoid split with prolonged stenting. Much of the subsequent work on laryngeal stenosis was performed in children because a growing patient population was created by the prolonged intubation of neonates. In 1971, Grahne (23) published a modification of the Rethi procedure. In 1972, Fearon and Cotton (24) introduced a new procedure developed in primates that successfully corrected subglottic stenosis in pediatric patients using grafts to increase the airway lumen.

Open surgical techniques for reconstruction of the airway compromised by laryngotracheal stenosis are usually considered in patients who are tracheotomy dependent and in patients who do not have a tracheotomy but who have significant exercise intolerance or sleep disturbance.

Otolaryngologists should have several open surgical techniques in their armamentarium to enable successful management of a variety of pathologic conditions (Table 90.6). Airway surgery should be tailored to the specific pathology of each patient, as no single procedure can adequately deal with all manifestations of laryngotracheal stenosis.

Anterior Cricoid Split

The anterior cricoid split procedure can be used instead of tracheotomy in the neonate who has failed extubation (Fig. 90.2). Table 90.7 outlines suggested criteria for this procedure. It is important to eliminate other causes of airway obstruction, such as laryngomalacia, tracheomalacia, choanal atresia, and retrognathia. Management in this age group requires careful endoscopic examination and management of reversible conditions (e.g., subglottic edema, laryngeal granulation) by intubation, steroid therapy, or laser excision. More severe laryngeal injury, especially with extensive mucosal injury, may be treated with an anterior cricoid split, allowing extubation without tracheotomy (25). Because the level of the anterior commissure in the infant lies at the junction of the upper two-thirds and lower one-third of the thyroid cartilage, the anterior laryngofissure should only extend to the lower one-third of the thyroid cartilage. The infant requires intubation for 7 to 10 days following the split, although this time period may be reduced if a thyroid alar cartilage cap is placed over the split site. In our experience, the addition of a thyroid alar graft offers the potential advantage of higher success rates while adding little operative morbidity (26).

TABLE 90.6 TREATMENT LARYNGEAL STENOSIS

Medical
- Prevention
  - Experienced intubation personnel
  - Correctly sized endotracheal tube
- Infectious diseases
  - Diagnostic biopsy
  - Prompt treatment
- Supportive therapy
  - Pulmonary toilet
  - Humidification
  - Antibiotics, steroids

Surgical
- Preoperative workup
  - Secure airway, endoscopic evaluation of airway sizing
  - Cardiac and pulmonary function
  - Gastroesophageal reflux assessment
  - Functional endoscopic evaluation of swallowing
  - Radiographic studies
- Grade I or II stenosis, unilateral lesions (e.g., hemangioma, cysts, or thin webs)
  - Dilatation
  - Division
  - Micro-trapdoor flaps
  - Endoscopic resection
  - Laser surgery
- Failed extubation stenosis
  - Anterior cricoid split (e.g., newborn, infant)
  - Tracheotomy (e.g., O_2 requirement, severe lung disease)
- Grades II, III, and IV stenoses, circumferential lesions, thick webs, failed endoscopic therapy, loss of cartilaginous framework
  - Anterior cartilage graft (e.g., moderate stenosis, stomal collapse)
  - Anterior graft/posterior split with stent (e.g., severe stenosis)
  - Anterior/posterior split with lumen augmentation (i.e., cartilage, myoperiosteal flaps)
  - Cricotracheal resection

Laryngotracheal Reconstruction–Anterior Cartilage Graft

For grade I or grade II subglottic stenosis, an anterior autogenous costal cartilage graft is a highly effective method for reconstruction of the airway when endoscopic management is either not possible or unsuccessful (27,28) (Fig. 90.3). This approach may also be effective in selected grade III lesions. A boat-shaped flanged graft is placed between the divided anterior lamina of the cricoid cartilage and, if required, may extend inferiorly across two or three tracheal rings. It should not transgress the anterior commissure. Other options for graft material include thyroid alar and auricular cartilage, although neither has the same structural integrity as costal cartilage.

Laryngotracheal Reconstruction–Posterior Cartilage Graft

Posterior glottic stenosis is a common sequela of prolonged intubation and is often misdiagnosed as bilateral cord paralysis. There may be associated fibrosis or ankylosis of the cricoarytenoid joints. A posterior costal cartilage

TABLE 90.7 CRITERIA FOR PERFORMING AN ANTERIOR CRICOID SPLIT PROCEDURE

Two or more extubation failures secondary to laryngeal pathologic conditions
Child weighs more than 1,500 g
No assisted ventilation for 10 d before evaluation
Supplemental O_2 requirement <30%
No congestive heart failure for 1 mo before evaluation
No acute upper or lower respiratory tract infection at the time of evaluation
No antihypertensive medication for 10 d before evaluation

Adapted from Cotton RT, Seid AB. Management of the extubation problem in the premature child: anterior cricoid split as an alternative to tracheotomy. *Ann Otol Rhinol Laryngol* 1980;89:508.

graft placed after division of the posterior cricoid lamina may be performed as a single- or two-stage procedure (29). A narrow graft (less than 6 mm) is usually adequate and excessive augmentation risks aspiration. The same technique is employed for grade II or III subglottic stenosis with primarily posterior cricoid scarring. Although a complete laryngofissure allows excellent access to the posterior cricoid, particular care should be taken to both accurately divide and reconstruct the anterior commissure to ensure perfect cord alignment and to minimize the risk of long-term vocal dysfunction. It is possible to split the posterior cricoid without a laryngofissure, even in a neonate, but placing sutures to stabilize a cartilage graft in the posterior cricoid is very challenging in a younger child if a laryngofissure is not performed. An alternative is the placement of a

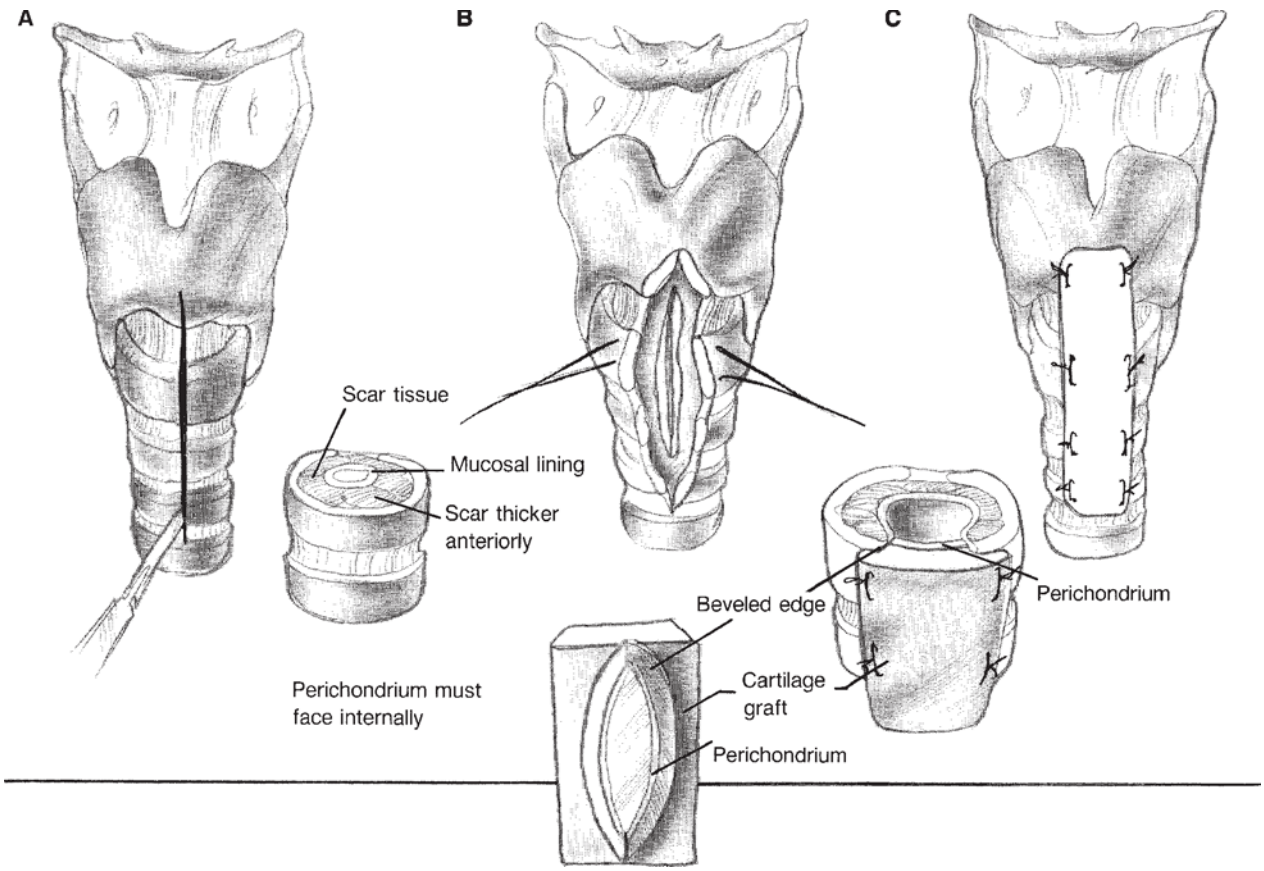

Figure 90.3 Anterior laryngofissure with anterior augmentation. **A**: Vertical incision (inferior to the cords) through the thyroid cartilage, cricoid, and upper tracheal rings. **B**: Beveled and elliptical cartilage graft. **C**: Cartilage graft in place with Vicryl sutures.

flanged posterior cartilage graft, where stability is such as to not require sutures. This procedure may also be performed using an endoscopic approach. The posterior cricoid plate is divided endoscopically with cold instrumentation or lasers. The graft is then placed endoscopically. This may be performed with or without a tracheotomy (30)

Laryngotracheal Reconstruction–Anterior and Posterior Cartilage Grafts

Grade III and grade IV subglottic stenoses usually require anterior and posterior costal cartilage grafting. After placement of the posterior cartilage graft, the anterior airway can then be closed over an appropriately sized endotracheal tube to estimate the size of the anterior graft required. If the anterior cricoid can be closed without tension, then an anterior graft may not be required. A variation of this procedure is an anterior graft with a posterior split of the cricoid lamina—an option usually limited to younger children. Grade IV subglottic stenosis usually requires more than one procedure to achieve decannulation using cartilage expansion techniques (31)

Cricotracheal Resection

An alternative to anterior/posterior cartilage grafting is cricotracheal resection (32,33) (Fig. 90.4). The concept is the removal of the diseased portion of the airway with the introduction of healthy tissue into the subglottis. This is a more technically challenging procedure than anterior/posterior cartilage grafting and is therefore usually reserved for patients with severe (grade III or IV) subglottic stenosis. It also has particular application in the reconstruction of the airway that has failed previous laryngotracheal reconstruction. There is a higher chance of achieving decannulation after a single procedure with cricotracheal resection than with standard cartilage augmentation laryngotracheal reconstruction. The advantages of the procedure include glottic sparing, avoidance of donor site morbidity, and a near normal appearing and mucosalized airway. The disadvantages include a risk to the recurrent laryngeal nerves and anastomotic dehiscence. Patient selection is important, and subglottic scarring within 3 mm of the vocal folds is a relative contraindication.

Slide Tracheoplasty and Cervical Slide Tracheoplasty

For children with complete tracheal rings, slide tracheoplasty is the recommended surgical intervention (34). This approach yields significantly better results than other tracheal reconstruction techniques and is applicable to all anatomic variants of complete tracheal rings. Slide tracheoplasty is generally performed on cardiopulmonary bypass

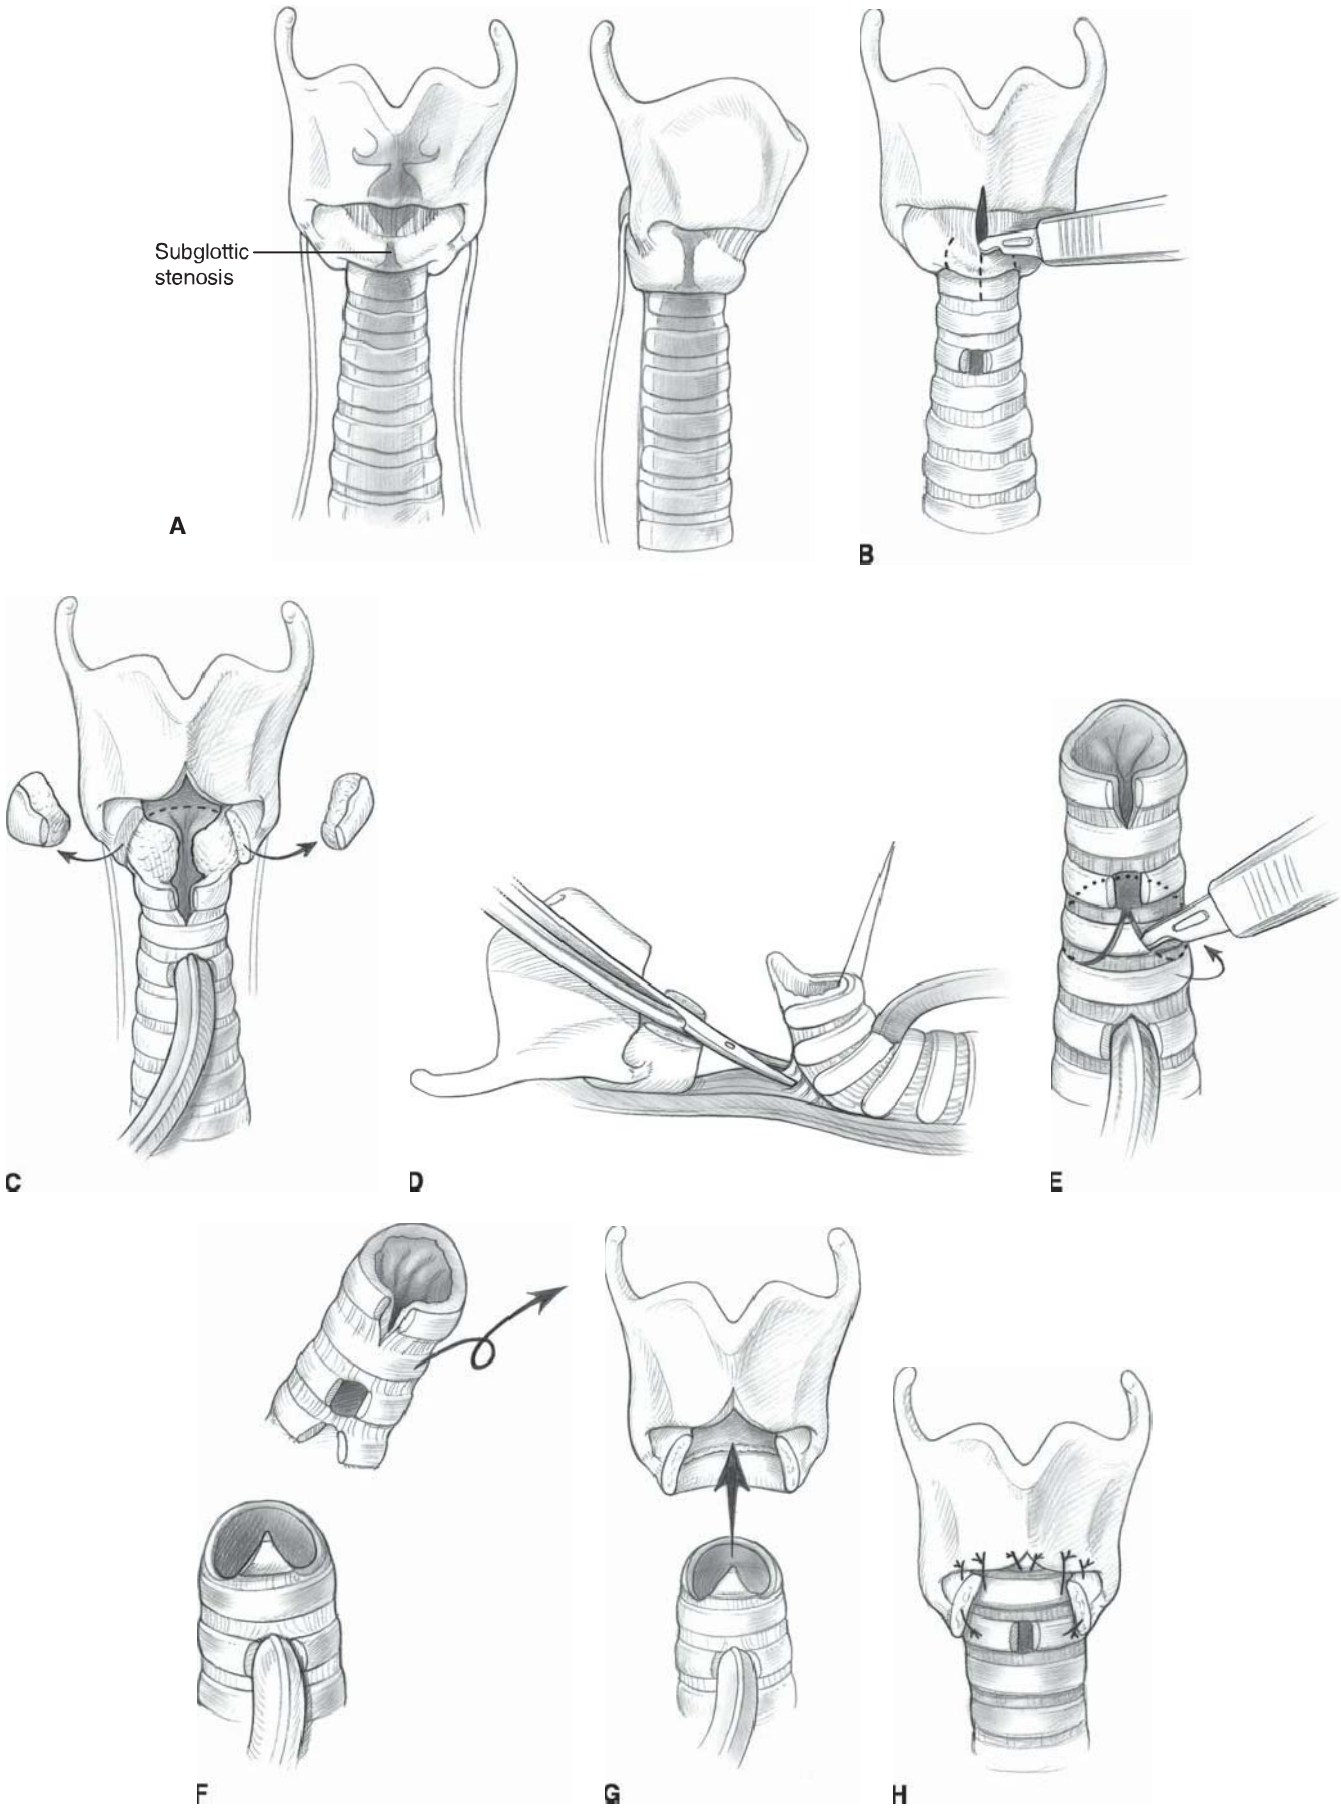

Figure 90.4 Cricotracheal resection. **A**: Stenotic segment for resection. **B**: Anterior cricoid split. **C**: Excision anterior cricoid lamina. **D**: Elevation of trachea off esophagus. **E**: Stenotic upper trachea for sacrifice. **F**: Removal stenotic upper trachea. **G**: Telescoping trachea into posterior cricoid lamina. **H**: Thyrotracheal anastomosis.

or ECMO through a midline sternotomy. Cardiopulmonary bypass offers a number of advantages: (a) the heart and lungs can be decompressed, allowing better access to the trachea during the procedure; (b) possible cardiac anomalies can be addressed at the time of surgery; and (c) during bypass, ventilation is not a concern while working in the exposed airway.

As originally described by Tsang et al. (35) and popularized by Grillo et al. (36), the slide tracheoplasty overlaps stenotic segments of the trachea, shortening the trachea, but doubling the circumference and diameter of the stenotic area. After the patient is placed on cardiopulmonary bypass and the airway is exposed, intraoperative bronchoscopy is performed to establish the upper and lower limits of the segment of complete rings, with a 30-gauge needle placed through the anterior tracheal wall and visualized bronchoscopically. The length of the stenosis is measured and the trachea is transected at the midpoint of the stenosis. The trachea is mobilized, taking care to preserve the lateral vascular attachments to the trachea. The posterior wall of the distal segment is divided until the trachealis muscle is encountered or the carina is reached. The anterior wall of the proximal segment is divided until beyond the most proximal complete ring. The segments are then slid over each other using a running double-armed 5.0 or 6.0 PDS suture (34). Most patients are left intubated for 24 to 48 hours postoperatively. Because secretions are often collected at the anastomosis, the airway requires humidification for several weeks. Possible postoperative complications include dehiscence and lateral anastomotic prominence (referred to as "figure-of-8" deformity).

Cervical slide tracheoplasty is a modification of the classic slide tracheoplasty. This operation offers an alternative to the classic technique for addressing problems in the upper two-thirds of the trachea (i.e., long-segment stenosis). Unlike the classic slide tracheoplasty, the cervical slide procedure is usually performed without the need for cardiopulmonary bypass, and is performed through a cervical neck incision.

Stenting Options

The primary decision that needs to be made in terms of stenting is the required duration of stent placement. The more unstable the airway reconstruction (e.g., following an anterior/posterior graft), or if there is a history of previous failed reconstruction, the longer the period of stenting required. Long-term stenting may be achieved with a T-Tube (Montgomery or Hood) or a wired-in metal tracheotomy tube within a Teflon stent (Aboulker or Cotton-Lorenz) (Fig. 90.5). Although once the mainstay of laryngotracheal reconstruction, the wired-in stent has become an increasingly rare method of postoperative airway stabilization. Generally, in children younger than 4 years, a T-Tube is best avoided because T-Tubes with less than an 8-mm outer diameter carry a higher risk of mucus occluding the lumen of the tube. Shorter-term stenting may be adequately achieved with a suprastomal Teflon stent, but this should ideally be removed after several weeks to prevent stenosis occurring between the distal end of the stent and the tracheotomy tube. Newer generation silicone suprastomal stents carry less risk of inducing stenosis at the distal tip of the stent (29).

If the period of stenting is less than 2 weeks and lung function is adequate, consideration may be given to a single-stage procedure, using an endotracheal tube as a stent. This technique is highly dependent upon access to a first-class intensive care unit. Paralysis is best avoided to allow the child an opportunity to maintain his or her own airway in the event of an accidental extubation. Most children younger than 3 years require sedation, whereas many children older than 3 years do not. The period of intubation depends upon the surgery performed and may vary from 1 day for selected anterior cartilage grafts to 14 days for an anterior/posterior cartilage graft.

In some circumstances, a stent may not be required for a two-stage reconstruction. An anterior costal cartilage graft laryngotracheal reconstruction rarely needs a stent, and selected cricotracheal resections may not need a stent.

DECISION MAKING

Before deciding on an open surgical reconstructive technique, conservative endoscopic treatment of laryngeal stenosis should be considered. This approach may include endoscopic dilatation, laser therapy, tissue removal by endoscopic microsurgical techniques, local and systemic steroid therapy, and antibiotic therapy. If these techniques are unsuccessful, open reconstruction of the airway can be considered.

Several factors may influence the timing of surgical correction in children. Patients with acquired laryngeal stenosis caused by long-term intubation frequently have underlying chronic pulmonary disease. Lung disease, such as bronchopulmonary dysplasia, must be addressed medically before surgical correction of the airway. In many children with laryngeal stenosis, other congenital or acquired anomalies require surgical repair. Reconstruction of the airway can be delayed until the other surgical procedures are completed because the existing tracheotomy tube allows easy and safe access to the airway.

In adults and children, any indication of significant GERD should be corrected medically (e.g., histamine [H_2 blockers, antacids] or surgically [e.g., Nissen fundoplication]) before airway reconstruction is undertaken. If this is not successfully treated before reconstruction, the reconstructed airway may suffer repeated injury by acidic gastric contents, causing granulation tissue and further stenosis. Patients with EE also require similar intervention and stabilization prior to undergoing airway surgery.

The variety of open surgical procedures available for reconstruction, including some that are not outlined here, allows the otolaryngologist to manage the stenotic larynx regardless of etiologic factors. Severe stenosis frequently requires more than one surgical correction for successful reconstruction. Therefore, early stenotic lesions should be treated aggressively to maintain an opening in the airway.

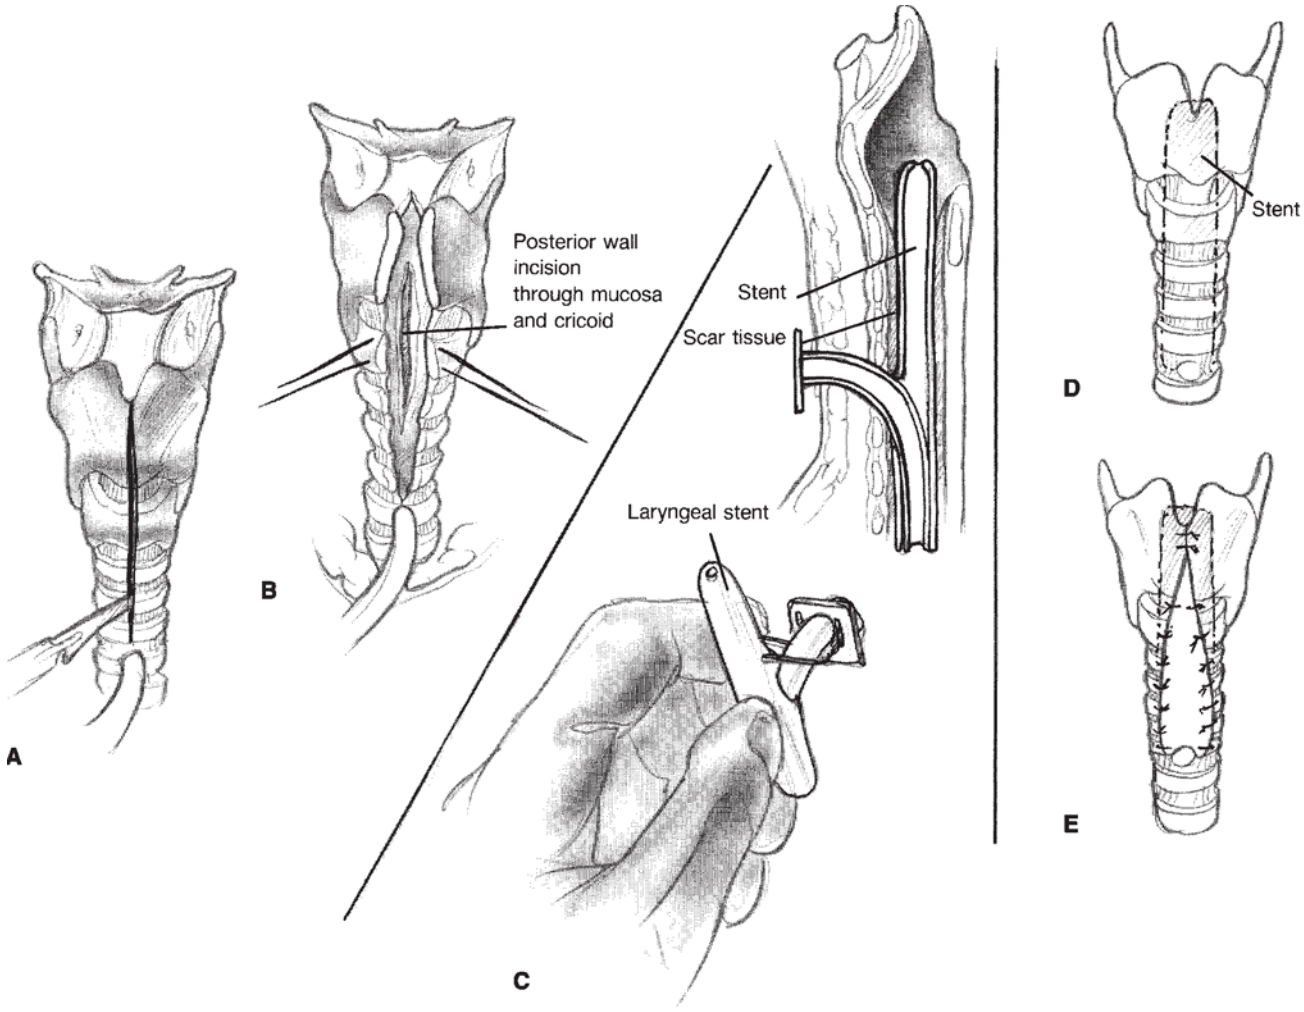

Figure 90.5 Anterior laryngofissure with posterior cricoid lamina split. **A**: Vertical midline laryngofissure from the thyroid notch to the proximal trachea or stoma. **B**: Division of posterior cricoid. **C**: Holinger metal tracheotomy tube wired to Aboulker or Cotton stent. **D**: Stent and tracheotomy tube in place. **E**: Stent and tracheotomy tube in place with an anterior costal cartilage graft.

COMPLICATIONS

Complications related to airway reconstruction may occur intraoperatively, early postoperatively, or late postoperatively. Intraoperative complications include hypoxia, pneumothorax (usually related to harvesting rib cartilage), and pneumomediastinum. Similar problems may occur postoperatively, as may wound infections, graft displacement, stent dislodgement, aspiration, and mucus plugging of the tracheotomy tube. Single-stage reconstruction carries particular risks, including endotracheal tube obstruction, unplanned extubation, glottic edema, and narcotic withdrawal.

All patients who are discharged with tracheotomy tubes should be taught tracheotomy care and given spare tracheotomy tubes, including one a size smaller than that which resides in the patient in case of difficulty with reinsertion in an emergency. The family should be instructed in tracheotomy care, including suctioning and changing the tracheotomy tube.

EMERGENCIES

Emergent complications in the care of laryngeal stenosis include airway obstruction, aspiration of a wire or stent, hemorrhage or hematoma formation, and pneumothorax with resulting respiratory distress.

Airway obstruction may be caused by mucous plugs or granulation tissue. Humidified air should be provided, and changing of the inner cannula or tracheotomy tube should be performed regularly to prevent plugging. Mucous plugs should be carefully suctioned. Granulation tissue may be treated with steroids (e.g., dexamethasone, 0.5 mg/kg/d to a maximum of 20 mg/day) by mouth or with topical or aerosolized steroid/antibiotic drops such as ciprofloxacin/dexamethasone through the tracheotomy tube, depending on the site of granulation tissue. If granulation tissue is causing significant obstruction, the patient may need to be admitted and closely monitored during therapy. Solitary pedunculated granulomas may

be safely removed with forceps during removal of the stent or during an interval examination postoperatively. These patients may be placed on a short-pulsed dose of oral steroids, oral antibiotics, proton pump inhibitors, and topical ciprofloxacin/dexamethasone through the tracheotomy tube.

To avoid some of these complications, the surgical technique should include the use of drains and, in open airway procedures, closure of the skin that allows the escape of air. A radiograph of the chest should always be obtained postoperatively for open reconstructive procedures. If an anterior costal cartilage graft is harvested, sterile saline should be placed in the wound and a positive pressure breath given to determine the possibility of an air leak. Good surgical technique with careful hemostasis and education of ancillary personnel and family can minimize these emergencies.

HIGHLIGHTS

- The narrowest part of the airway in the pediatric patient is the subglottis; in the adult, it is the glottis.
- Symptoms of obstruction differ by location. Supraglottic stenosis presents with inspiratory stridor. Glottic and subglottic stenoses present with biphasic stridor. Lower airway obstruction presents with expiratory stridor.
- Endoscopy is necessary for diagnosing laryngeal stenosis, although lateral and anteroposterior neck radiographs, CT, and fluoroscopy may also contribute information.
- Acquired laryngeal stenosis is much more common than congenital stenosis and is usually more difficult to repair.
- The most important factor in preventing acquired laryngeal stenosis is intubation with an endotracheal tube that is the smallest size permitting adequate ventilation of the patient, while ideally maintaining a leak at less than 20 cm of water pressure.
- Dilatation is usually not successful for long-term management of "fixed" or firm stenosis.
- Successful repair of laryngeal stenosis requires careful evaluation of the patient as well as the airway. Patient factors include evaluation of pulmonary function, esophageal disease, and bacterial colonization. Airway factors include evaluation of the nasopharynx, supraglottis, trachea, and bronchi.
- GERD must be controlled prior to undertaking surgical repair of laryngeal stenosis.
- Measurement of the airway by endotracheal tubes is a reliable and objective method in the diagnosis and follow-up of laryngeal stenosis.

91 Pediatric Voice

Susan Baker Brehm *Melissa M. Statham*
Alessandro de Alarcón

Pediatric voice disorders comprise a broad spectrum of problems commonly encountered in pediatric otolaryngology practice. Epidemiologic reports estimate that more than 1 million children in the United States are dysphonic, with abnormalities in pitch, quality, and/or loudness (1–3). Given the potentially far-reaching impact that voice disorders may have on the psychosocial development of children, it is imperative that practitioners have a basic understanding of this growing field and a sound working knowledge of contemporary pediatric voice evaluation and management techniques (4,5). To this end, our chapter will present an overview of key voice-related concepts and clinical issues in children.

ANATOMIC CHANGES IN THE LARYNX DURING CHILDHOOD

The Laryngeal Framework

The pediatric larynx continually matures throughout childhood. Maturational changes are particularly rapid during the first several years of life and then gradually slow down until the larynx reaches maturity in young adulthood. Both the thyroid cartilage and the cricoid cartilage undergo significant changes in length, height, width, and weight, though these changes are more pronounced in males. The pediatric larynx is much higher in the airway than the adult larynx and gradually descends with age. In a neonate, the larynx is high in the neck, with the lower border of the cricoid cartilage approximately at the level of C3-C4. By age 2, it descends to approximately C5, and by age 15, it descends to C6-C7. This downward migration is associated with increasing separation between the hyoid bone and the thyroid cartilage, which are contiguous at birth.

Microstructure of the Vocal Fold

Two aspects of the developing pediatric vocal fold play an important role in voice: (a) the relationship between the arytenoid and the musculomembranous fold and (b) the layered vocal fold structure. In neonates, the proportion of the arytenoid and the musculomembranous fold is equal. Over time, this proportion changes, with the musculomembranous fold becoming two-thirds of the vocal fold. The layered structure of the lamina propria also significantly changes. From 2 to 11 months of age, the initial monolayer gradually becomes a bilayered structure. By age 7, it becomes an adult-like three-layered structure (6,7). Collectively, these anatomic and structural changes influence when a voice disorder manifests as well as a clinician's ability to evaluate and initiate treatment. The relationship between these changes and specific voice disorders will be discussed later in this chapter.

VOICE EVALUATION

Optimally, voice evaluation should be carried out in an interdisciplinary setting. This allows close collaboration between otolaryngologists and speech-language pathologists, thus facilitating a more thorough evaluation and the development of a comprehensive, well-coordinated management strategy. Also, it offers parents the convenience of decreasing the number of clinic visits for their child and the number of endoscopies performed.

A comprehensive voice assessment should include a medical history, an endoscopic or videostroboscopic examination, an acoustic evaluation, an aerodynamic evaluation, a perceptual evaluation, and often, a voice-related quality of life or handicapping evaluation. These combined tests provide clinicians with a global perspective on the disorder, facilitate the categorization of the disorder, and ultimately, play a role in treatment decisions.

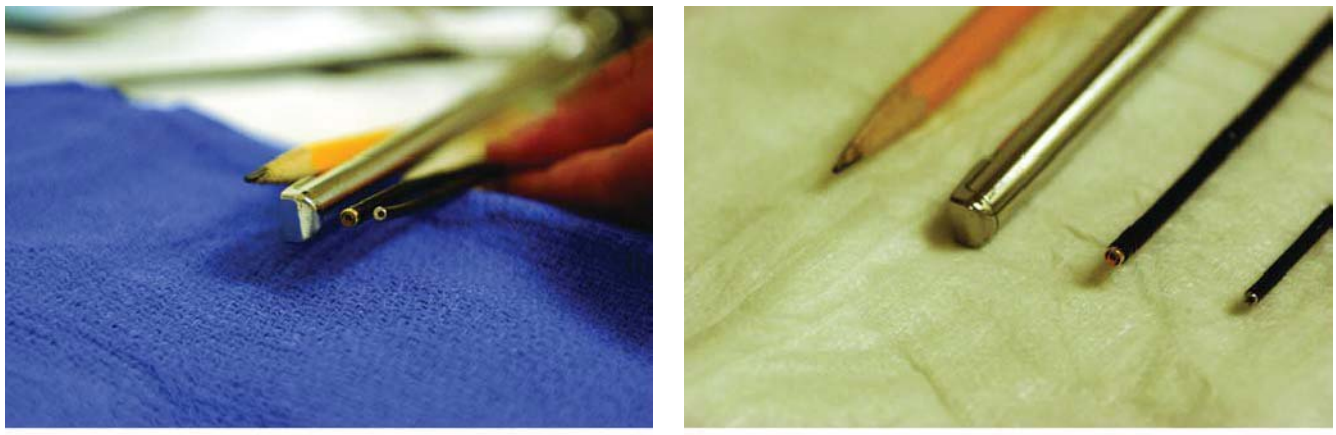
History

A thorough medical history often allows the clinician to establish a differential diagnosis before proceeding to the endoscopic examination. This history should include relevant information pertaining to the onset of the voice disorder, the sound quality of the voice, and conditions that may alter the sound quality. Prior intubation, prior airway surgery, and prior voice therapy as well as therapeutic approaches used in this therapy should also be documented. Associated symptoms such as coughing, throat clearing, and globus sensation should be noted.

Endoscopy and Videostroboscopy

A successfully performed pediatric endoscopy depends on the child's ability to cooperate during the examination. This is influenced by age, the presence of developmental delay, and the overall comfort level of the child (8). Successfully performing a videostroboscopy depends on whether the child is capable of sustaining a sufficiently long phonation. The choice of instrumentation must consider these two factors.

In most children, endoscopy/stroboscopy is well tolerated and easily performed. Pediatric fiberoptic endoscopes (2.2 to 2.4 mm in diameter) are typically used for children younger than age 4. Although these scopes are well tolerated, they sacrifice image quality for comfort. Pediatric chip-on-the-tip endoscopes (3.1 to 3.2 mm in diameter) provide significantly improved image quality and are generally tolerated by children age 4 and older. These endoscopes allow for the evaluation of connected speech, which plays a role in a number of pediatric voice disorders (Fig. 91.1A and B and Fig. 91.2A and B).



Rigid endoscopy is often reserved for more cooperative children, which typically includes those who are older than age 7. It can be performed using a standard adult rigid stroboscope, a smaller Hopkins rod, or a pediatric rigid stroboscope. These scopes offer better imaging of the vibrating vocal fold than fiberoptic endoscopes.

Videostroboscopy can be employed with either rigid or flexible endoscopes. This technique differs from standard endoscopy, as it uses a strobe light source that is synchronized with the acoustic signal produced during phonation. Furthermore, a video system is used to record the examination. The resulting images show a slow-motion glottal cycle artificially assembled from multiple glottal cycles. These images can then be reviewed to assess vocal fold vibration. Given that videostroboscopy depends on the ability of the child to cooperate, it is often difficult to obtain. Some children may be unable to provide sustained phonation of sufficient duration to allow the strobe light source to synchronize. (For a more in-depth discussion of videostroboscopy, see Chapter 65.)

Acoustic and Aerodynamic Evaluations

Acoustic and aerodynamic evaluations are best performed in a sound-treated, quiet room or a sound booth. Several software programs are available for the completion of the acoustic assessment such as the KayPENTAX computerized speech lab (Lincoln Park, New Jersey). Typical acoustic measures include maximum phonatory frequency range, fundamental frequency, loudness, perturbation (jitter and shimmer), and acoustic signal typing. These measures assist in characterizing voice problems and in helping the clinician make decisions regarding therapeutic interventions (9).

The aim of the aerodynamic assessment is to describe the relationship of the voice disorder to aspects of airflow and pressure during phonation. This assessment measures the rate of airflow through the vocal folds during phonation, breath support, and estimated subglottic pressures. Optimally, this assessment is performed by a speech-language pathologist using instrumentation available through Glottal Enterprises (Syracuse, New York) or KayPENTAX (Lincoln Park, New Jersey).

Perceptual Evaluation of Voice

A perceptual evaluation can best be described as a standardized expert rating of how voice is perceived. The two most frequently used perceptual tools are the GRBAS (Grade, Roughness, Breathiness, Asthenia, Strain Scale) and the CAPE-V (Consensus Auditory-Perceptual Evaluation of Voice) (10). The CAPE-V evaluation comprises six core perceptual aspects of voice, which include overall severity, roughness, breathiness, strain, pitch, and loudness. Each of these elements is rated using a visual analog system. Ideally, the rating should be performed by at least two speech-language pathologists with expertise in voice disorders.

Voice-Related Quality of Life/Handicapping

Voice-related quality-of-life/handicapping assessments are designed to measure the impact of a voice disorder on a child's daily life. This assessment is more complicated in children than in adults because parental perspectives may be quite different from those of children. These perspectives may be colored by factors such as the child's past airway history, the duration of the voice disorder, and societal influences.

Instruments that have been validated and are widely used include the PVOS (Pediatric Voice Outcomes Survey), the PVRQOL (Pediatric Voice-Related Quality of Life), and the pVHI (Pediatric Voice Handicap Index). A fourth instrument currently being developed is the voice-related PEDS QL 4.0 (Physical, Emotional, Social, Work/School Functioning) (11–15). This differs from the above-mentioned instruments in that it takes into account both the parent's and child's perspectives. At least one voice-related quality-of-life evaluation should be included in the battery of tests used by the practitioner in assessing a voice disorder.

PEDIATRIC VOICE DISORDERS

Laryngopharyngeal Reflux and Eosinophilic Esophagitis

The most common esophageal disorders associated with pediatric dysphonia are laryngopharyngeal reflux (LPR) and eosinophilic esophagitis (EE) (16,17). Children with these disorders generally present with chronic coughing, throat clearing, and globus sensation. These symptoms are often worse in the morning and may improve during the course of the day. The dysphonia is usually perceived as a rough, harsh-sounding voice. Voice quality fluctuates; however, it typically worsens with voice use. Although endoscopic findings are often variable, they may include vocal fold edema, erythema, vocal fold nodules, interarytenoid pachydermia, pseudo-sulculus vocalis, and thickening of the vocal fold cover (Fig. 91.3A–C).

Patients with a suspected diagnosis of LPR or EE are often initially managed with a proton pump inhibitor for a 1- to 2-month period. Parents should be advised that this medication must be taken on an empty stomach 30 minutes before a meal. Most important, it should be given at times which offer maximal convenience and consistency to both the parent and the child. Additionally, the clinician should discuss dietary changes and lifestyle modifications with patients and their families (Chapter 66).

When the dysphonia and related symptoms persist, the patient should be referred to a gastroenterologist for an esophagogastroduodenoscopy (EGD), impedance probe testing, and biopsies. These diagnostic tests will distinguish between LPR, EE, and other disorders. Optimally, otolaryngologists and gastroenterologists work collaboratively to manage these patients. For a detailed discussion of the management of patients with EE, see Chapter 59.

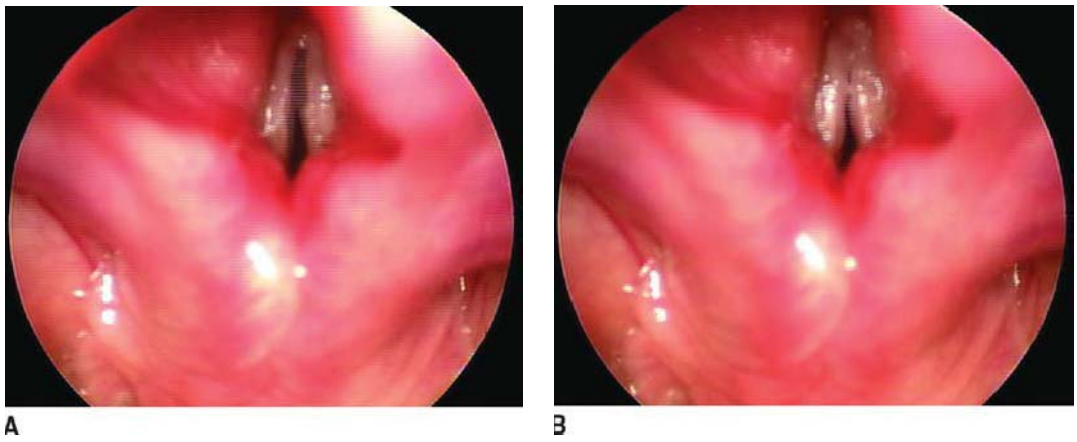

Figure 91.3 Endoscopic views of a child with reflux-induced dysphonia. (**A**,**B**) show sequential images from stroboscopy. (**C**) shows operative microlaryngoscopy performed during an EGD, impedance probe, and biopsies, which confirmed significant reflux.

Vocal Fold Nodules, Cysts, and Polyps

Vocal fold nodules are the most commonly encountered cause of pediatric dysphonia (5% to 40%) (18). Patients generally present with a harsh, breathy voice. They often have limited pitch range and may have voice breaks and aphonia at specific pitches. Also, voice quality often worsens with heavy voice use. These children may be either heavy voice users or vocal abusers who frequently scream and yell. Endoscopic examination often reveals fairly symmetric bilateral lesions in the midmembranous vocal fold. During vocal fold closure, a typical hourglass closure configuration is often seen. (Fig. 91.4A and B) The location and size of the lesions variably affects mucosal wave, vocal fold vibration, and pitch. The perceptual assessment of voice quality varies from mild-to-severe dysphonia (19,20).

The voice perception of patients with vocal fold cysts and polyps is often similar to that of patients with vocal fold nodules. In some cases, however, there may be a history of an acute phono-traumatic event associated with the development of dysphonia. Cyst and polyps are much less common than nodules. Endoscopic examination often demonstrates a large unilateral lesion and a smaller contralateral reactive lesion (Fig. 91.5A–D). As with vocal fold nodules, the size

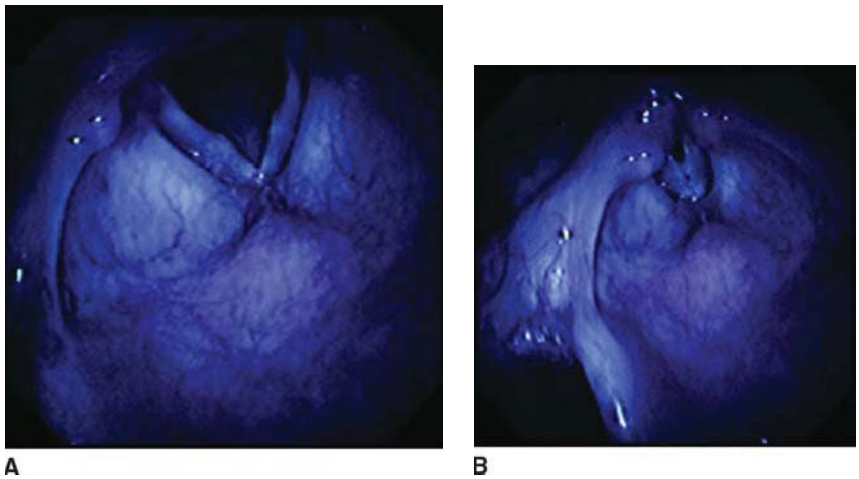

Figure 91.4 Vocal fold nodules. **A:** Open glottis with midmembranous nodules. **B:** Hourglass closure during phonation.

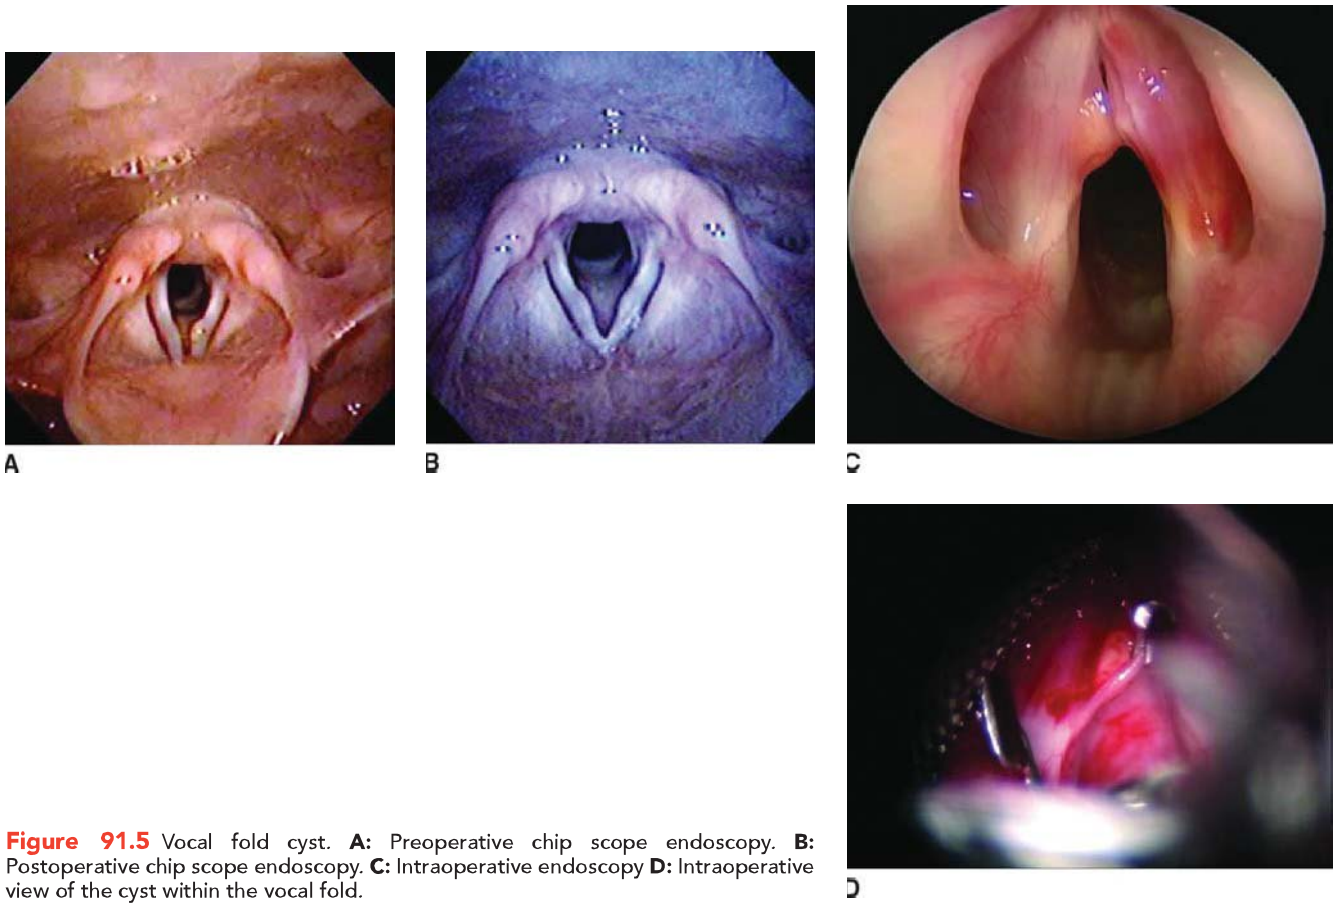

Figure 91.5 Vocal fold cyst. **A:** Preoperative chip scope endoscopy. **B:** Postoperative chip scope endoscopy. **C:** Intraoperative endoscopy **D:** Intraoperative view of the cyst within the vocal fold.

and location of the lesion are often related to the effect on voice. Vocal fold cysts can be mucous or epithelial, and their location can vary from fairly superficial to very deep within the vocal fold. Vocal fold polyps are often exophytic, more pedunculated, and may have an obvious vascular supply. In some cases, imaging of pediatric vocal fold nodules, cysts, and polyps may not accurately differentiate these lesions. The lack of a uniformly accepted nomenclature in pediatric laryngology may also hamper diagnosis and treatment. For a more in-depth description of these benign lesions, see Chapter 68.

Nonoperative Management of Vocal Fold Nodules, Cysts, and Polyps

The initial management of children with vocal fold nodules, cysts, and polyps often involves a course of voice therapy with a speech-language pathologist with expertise in voice disorders (4,5,19,21). Most children who are 4 years of age or older and developmentally normal can actively participate in voice therapy. For children who are younger, developmentally delayed, or unable to participate, reassurance, vocal hygiene counseling, and scheduling routine office follow-up visits may be more appropriate. Typically, voice therapy consists of 10 to 12 sessions over a 2- to 3-month period. After completion of this protocol, we recommend reevaluation of the child to assess voice changes that have occurred as well as the parent's and child's perceptions of changes. The speech-language pathologist plays a crucial role in relating information regarding compliance with voice therapy to the clinician. This information is helpful in that it serves as an indicator of the feasibility of a successful surgical intervention, which requires ongoing postoperative therapy.

Operative Management

Operative management is considered for patients who show little or no improvement in voice quality after completing a course of voice therapy. This approach may consist of an endoscopy to confirm the diagnosis or to determine the possible esophageal contribution to the disorder (i.e., LPR or EE).

Surgical removal of pediatric vocal fold lesions is controversial, and studies comparing nonoperative and operative management are limited (22). Moreover, these studies often show selection bias in patients who undergo surgery. Patients with vocal fold cysts and polyps are more likely to undergo surgical removal than those with vocal nodules because they are less likely to improve with voice therapy. However, the decision to have the child undergo elective surgery should be made jointly by the surgeon, the child, and the caregivers. Children who are compliant with medical therapy, who have a significantly compromised voice-related quality of life, and who have no significant comorbidities that may affect surgical outcome are good surgical candidates. In addition, the surgeon must also consider the child's ability to participate

in the prescribed therapy and the child's past behavior in voice therapy. To decrease the likelihood of a poor voice outcome, surgery should be delayed on children who cannot yet participate in therapy or who are noncompliant.

Surgery should be performed by clinicians who have received training in microflap techniques and should use high-magnification microscopy and microlaryngeal instrumentation. Lesion removal should be performed with the aim of maximally preserving the superficial lamina propria and normal vocal fold architecture (see Chapter 68). The timing of surgery in children is often dictated by the need for postoperative voice rest and how this may affect the child's school schedule. In view of these considerations, surgery is often performed during the summer or during holiday breaks. Relative contraindications to surgery include uncontrolled medical comorbidities such as reflux or EE, poor compliance with voice therapy, significant vocal abuse, and poorly controlled asthma or allergies.

Recurrent Respiratory Papillomatosis (RRP)

Although children with RRP frequently present with airway distress and airway obstruction, a subset of children presents with hoarseness (23). These children often require less frequent surgical debridement. Children who present with dysphonia related to RRP often have a characteristic harsh, raspy voice with voice breaks and periods of aphonia. On endoscopy, papillomatosis is characterized by sessile or pedunculated frond-like growths, which can be seen anywhere within the confines of the larynx (subglottis to supraglottis). The characteristically normal vocal fold structure is often obscured when there is vocal fold involvement. Management involves surgical removal of the papilloma (Chapter 94). To ensure optimization of voice outcomes, utmost care should be taken in using tissue-sparing techniques. To prevent webbing, the surgeon should be mindful of anterior commissure papilloma.

Children with RRP show varying degrees of dysphonia following surgery. Despite the need for frequent surgical intervention, many of these children have surprisingly good voice outcomes (24,25).

Unilateral Vocal Fold Paralysis

Unilateral vocal fold paralysis is more common than bilateral paralysis, and because of the longer course of the left recurrent laryngeal nerve (RLN), left-sided paralysis is more common than right-sided paralysis (4,5). Associated symptoms are typically a weak or breathy cry or a breathy voice quality. Some patients have diplophonia (two voice pitch sounds). To improve glottic closure, some patients compensate by using higher pitch speech. Other patients have frequent bouts of pneumonia or coughing and choking with the ingestion of liquids, which is consistent with aspiration. Dyspnea may be a common complaint; however, this is generally breathlessness and air hunger related to the loss of airway resistance during phonation. The medical history may reveal severe upper respiratory infection, patent ductus arteriosus ligation, congenital heart surgery, anterior approach cervical spine surgery, thyroid surgery, mediastinal surgery, tracheoesophageal repair, or airway surgery (tracheal resection or cricotracheal resection). Children with decreased pulmonary function or those who have undergone recent cardiac surgery are unlikely to compensate for aspiration caused by the vocal fold paralysis. Children with malignancies along the course of the RLN may present with unilateral vocal fold paralysis caused either by pressure on the nerve or direct nerve involvement. Additionally, several case reports suggest an association between vocal fold paralysis and the chemotherapeutic agent vincristine.

Endoscopy and stroboscopy will reveal the paralytic vocal fold. (See Chapter 69 for additional stroboscopic findings.) The position of the fold during phonation and the arytenoid position should be noted during the endoscopic examination, as both can play a role in treatment decisions.

Laryngeal electromyography (LEMG) evaluates electrophysiologic activity in the larynx and may offer useful information regarding the likelihood of the return of purposeful vocal fold function. Additionally, it may help in determining the location of the nerve injury. The reported prognostic value of LEMG in adults is variable; however, the utilization of discreet LEMG criteria improves the accuracy of prognosis for the recovery of vocal fold motion (26). In children, difficulty in electrode placement because of tolerance levels and smaller muscle size is a limitation. In view of this, the role of LEMG in the evaluation of pediatric vocal fold paralysis has not yet been established and is currently being studied (27). To date, there is very little data on the use of LEMG in children.

Treatment of glottal insufficiency is generally determined by patients' symptoms, including the adequacy of their cough, the presence of aspiration, and the degree of phonatory dysfunction. In patients with a known cause of the vocal fold paralysis, a radiologic workup (computed tomography or magnetic resonance imaging [MRI]) is unwarranted. When the etiology of the paralysis is unknown, however, a radiologic study should be performed to evaluate the entire course of the RLN (from the skull base to below the aortic arch). Management strategies include observation, the use of temporizing measures, and longer-term therapeutic interventions. In patients with a minimal voice deficit, observation alone may be used while awaiting possible recovery of vocal fold function. Temporizing measures may be used in patients with a more significant voice deficit. These measures involve the use of short-acting injectable tissue fillers (injection medialization laryngoplasty). Several injectables with varying durations of effectiveness are available (28–30). These injectables include Radiesse Voice Gel, Restylane, and Cymetra (shortest-to-longest acting, respectively). In most children, injection laryngoplasty is performed in the operating room; however, cooperative teenagers may be able to tolerate an in-office procedure (28–30). Longer-term interventions include the injection of longer acting

tissue fillers such as Radiesse Voice and autologous fat (31). Data pertaining to long-term voice outcomes with the use of Radiesse Voice in children is scant. This injectable should be used with caution, as it can be improperly placed within the larynx. Furthermore, with all injectables, increased caution is warranted, as the pediatric vocal folds are small. Meticulous control and placement of an injectate is needed, as injection into the Reinke space will result in impaired vocal fold vibration and distortion of the free edge of the membranous vocal fold. Permanent medialization laryngoplasty with Gore-Tex or silastic is best reserved for children who have gone through puberty and who thus have a fully matured larynx (32). Delaying this procedure until puberty decreases the risk of needing revision laryngoplasty. Also, teenagers are more likely to tolerate an awake procedure, which improves the likelihood of a good voice outcome. Regardless of the material used for medialization, the margin of error is relatively small, and the surgeon should be skilled in the technique that is most suitable for the patient.

An approach that has recently gained wider interest for use in children is ansa-cervicalis to RLN reinnervation with simultaneous injection laryngoplasty (33). The use of this procedure is controversial in adults; however, a recent randomized control trial suggests that it may be advantageous in younger patients (34). The procedure leads to voice outcomes (stroboscopic examination and perceptual evaluation) that are similar to those associated with medialization laryngoplasty. Although reinnervation does not result in return of vocal fold function, it may provide improved tone to the denervated vocal fold and lead to a better position of the "paralytic" vocal fold during phonation. Another potential advantage of the use of reinnervation in children is that it may provide a durable, stable voice without an implant, and it is unlikely to interfere with laryngeal development. Although there are currently no large-scale studies using this approach in children, anecdotal evidence and case series suggest that this may be a viable long-term therapeutic option prior to puberty (35,36). Rigorous studies of voice and swallowing outcomes are needed to better determine the utility of this procedure. Reinnervation does not preclude the use of medialization laryngoplasty at a later date if a satisfactory vocal outcome is not achieved. The procedure requires an open neck approach with the child under a general anesthetic. It should be performed by a surgeon with competency in pediatric open neck surgery. Nevertheless, further research in this area is needed to better define how to incorporate this approach into current treatment algorithms.

Bilateral Vocal Fold Paralysis

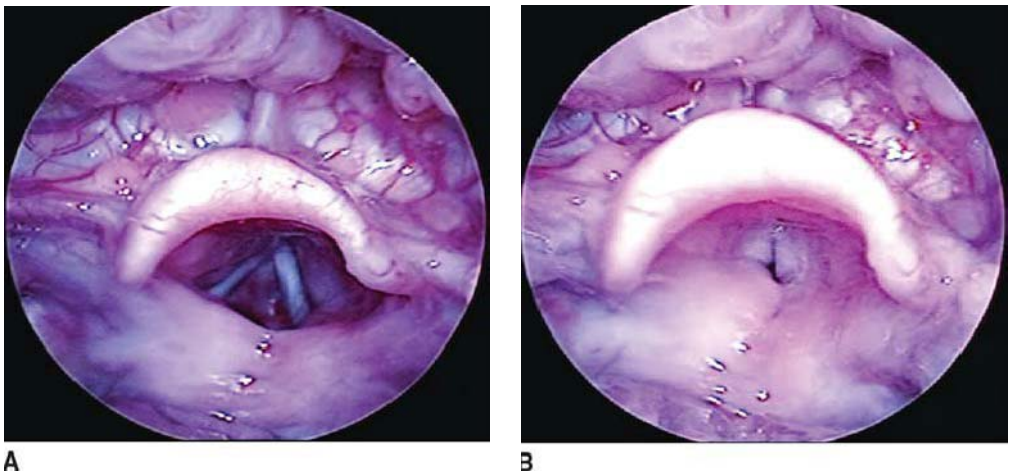
Bilateral vocal cord paralysis is sometimes associated with birth trauma, central nervous system abnormalities, and cardiovascular anomalies (37); however, most cases are idiopathic. Affected children usually present with stridor, airway obstruction, aspiration, a strong loud cry, and a good voice. Endoscopy/stroboscopy will reveal the vocal fold paralysis with the vocal folds in the paramedian or median position Also, inhalational collapse of the membranous vocal fold can frequently be visualized. It is often difficult to distinguish between bilateral paralysis, bilateral cricoarytenoid joint fixation, and posterior glottic stenosis on awake endoscopy. Operative endoscopy is often indicated in these cases to distinguish between these disorders. Management of airway obstruction is typically the focus of treatment. Therapeutic interventions include observation, tracheotomy, posterior cordotomy, arytenoidectomy, open or endoscopic vocal fold lateralization, or posterior cricoid expansion using costal cartilage grafting (38). Management of the bilateral paralysis always involves striking a balance in optimizing breathing, aspiration, and voice. Voice outcomes following any intervention have historically included a simple nonvalidated questionnaire or the surgeon's perceptions of the voice result. Important to note, parents' concerns regarding their child's airway obstruction often result in an underestimation of the actual impact of the voice disorder on their child. Further study using standardized voice assessments need to be performed in order to establish a more thorough understanding of the impact of surgery on voice outcome.

Laryngeal Webs

Congenital laryngeal webs result from a failure of airway recanalization during embryogenesis. In many children, webs extend into the subglottis. Given that 40% of children with a congenital laryngeal web also have velocardiofacial syndrome, all children with congenital webs should be evaluated for this syndrome (39). Children with significant webs typically exhibit symptoms of airway obstruction early in life. They often have a weak cry and can be aphonic or mildly dysphonic. Some patients, however, have good voices and strong cries and are minimally symptomatic. The length of the web can influence the vocal quality by altering voice pitch. Endoscopy reveals a web with variable thickness and vibratory qualities. Management of laryngeal webs is often focused on improvement of the airway. The thickness and the length of the web play a critical role in voice outcome following surgery. Treatment of thick webs often yields minimal voice improvement and, in some cases, may result in a worse voice. Postoperatively, the vibrating surface of the vocal fold is scarred and has poor vibratory characteristics. Treatment of thin webs often yields improvement in voice, as the postoperative vocal fold generally has better vibratory characteristics. Treatment of longer webs often has a positive impact on voice outcome, whereas treatment of shorter webs may result in only minimal improvement. Families should be counseled regarding these aspects of web management and should be advised as to specific management goals.

Functional Voice Disorders

The most common functional voice disorders seen in children include muscle tension dysphonia, psychogenic



aphonia, puberphonia, spasmodic dysphonia, and paradoxical vocal fold dysfunction (40–42). Children with these disorders may not demonstrate obvious anatomic pathology. Most functional voice disorders manifest during the teenage years, when children present with strained voices, problems with pitch changes, and occasional periods of aphonia. Endoscopy often reveals a structurally normal larynx and vocal folds with dysregulated laryngeal function. The management of children with most functional voice disorders is similar to the management of these disorders in adults. Therapeutic intervention by a speech-language pathologist and behavioral management by a psychologist are usually the mainstays of treatment (21). In contrast to other functional disorders, children with paradoxical vocal fold dysfunction have no voice complaints (43). These patients present with abnormal closure of vocal folds during inspiration and symptoms of airway obstruction. Symptoms are often episodic and occur with specific scenarios. Medical history often reveals that the symptomatic episodes are related to or exacerbated by stressful situations or physical exertion. Patients are frequently misdiagnosed with exercise-induced asthma; however, their symptoms will not respond to asthma medications. The prototypical child with paradoxical vocal fold dysfunction is a high academically functioning athletic female. Evidence also suggests that in some cases sexual abuse may be a contributing factor. As with other functional disorders, management involves the expertise of both a speech-language pathologist and a psychologist, who helps the patient gain insight into what triggers the condition. For recalcitrant cases, further workup and treatment are warranted and may include a MRI brain scan, Botox injection, and testing for myasthenia gravis (44).

Vocal Process Granulomas

Pediatric vocal process granulomas are uncommon and tend to be associated with intubation injury. Symptoms may include chronic coughing, chronic throat clearing, and throat pain. Perceptually, many patients exhibit borderline normal voice quality. Large granulomas can cause significant voice problems by preventing vocal fold closure, which results in a breathy dysphonia. Endoscopic examination reveals a vocal process lesion that is often unilateral. Hyperfunction of the lateral cricoarytenoid muscle is also frequently seen. Treatment includes the use of a proton pump inhibitor, the administration of steroids, and rarely, surgical debridement. Voice therapy plays a crucial role in managing the vocal hyperfunction that is often associated with these lesions.

Dysphonia Following Airway Reconstruction

Nearly 50% of children who undergo airway reconstruction will be dysphonic (45,46). Many children present with complaints years after airway reconstruction, typically during the teenage years. Complaints typically involve concerns about voice quality and loudness. Concerns related to voice quality often stem from social interaction with peers who may call attention to the dysphonia. Loudness concerns involve difficulty being heard in noisy environments and difficulty with voice projection and intelligibility. Postoperative voice disorders are highly variable, with patients exhibiting mild-to-severe dysphonia (47–49). Risk factors for poor voice outcomes include complete laryngofissure, posterior grafting, cricotracheal resection, and multiple airway reconstructions (47,50). On endoscopy, children demonstrate glottic, mixed glottic, or supraglottic phonation. (Fig. 91.6A and B) Patients with supraglottic and mixed glottic phonation will often have perceptually worse voice outcomes (49). Many of these patients have problems with glottic incompetence or diastasis (open glottis); typically, closure of the posterior glottis during phonation is problematic (51). Treatment protocols include voice therapy and, in select cases, surgical intervention. Management of these disorders is an ongoing area of research.

CONCLUSION

Pediatric voice disorders encompass a wide spectrum of conditions. Optimally, these conditions are managed by an interdisciplinary team with special expertise. A standardized approach using validated assessment instruments is recommended. Ongoing research is focused on attaining a more in-depth understanding of these disorders and on developing definitive treatment algorithms.

HIGHLIGHTS

- Pediatric voice disorders are optimally evaluated and managed by an interdisciplinary team with special expertise.
- Endoscopic evaluation of pediatric voice disorders is more commonly performed with flexible endoscopes.
- Vocal fold nodules are the most common cause of dysphonia in children.
- Functional voice disorders in children are primarily treated with voice therapy and behavioral management.
- Treatment algorithms for pediatric unilateral vocal fold paralysis may involve voice therapy, injection laryngoplasty, medialization laryngoplasty, or ansa-RLN reinnervation.
- Nearly half of pediatric patients who undergo airway reconstruction will have dysphonia.

ACKNOWLEDGMENT

The author wishes to acknowledge Aliza P. Cohen for assistance in writing this chapter.

92 Pediatric Tracheotomy

Jeffrey P. Simons

Airway problems in children are managed with a variety of techniques, depending on their cause, severity, chronicity, and anticipated outcome. The decision of whether a child would benefit from a tracheotomy is often made by the managing airway surgeon or otolaryngologist in the acute or emergent setting. More elective decisions regarding tracheotomy in children with chronic airway obstruction, respiratory failure, prolonged intubation, or the need for pulmonary toilet are often best made by a multidisciplinary team, including otolaryngologists, pulmonologists, critical care physicians, and general pediatricians.

Although pediatric tracheotomy is a relatively infrequently performed procedure, children undergoing tracheotomy still utilize a great deal of health care resources. One study estimated that 4,861 tracheotomies were performed in children in the year 1997 (1). The estimated aggregate inpatient hospital charges for children with tracheotomies in 1997 was about $952 million per year or about $200,000 per child, which would be about $1.34 billion per year or $282,000 per child in 2011 dollars (1). Hospital admissions for tracheotomy rank among the longest hospitalizations for all children with all problems (2). Pediatric patients with tracheostomy tubes have high hospital readmission rates, even 5 years after the tracheotomy was performed (2). Furthermore, parents caring for children with tracheostomy tubes experience considerable caregiver burden. Indeed, having a child with a tracheostomy tube can affect caregivers' emotional well-being, as well as have a significant economic impact on the family (3,4). In one study, caregivers of children with tracheostomy tubes reported adverse effects on many aspects of their quality of life, including sleep, relationships, social life, and ability to work (4).

Although the terms "tracheotomy" and "tracheostomy" have been used interchangeably in the past, they have distinct meanings. The term "tracheotomy," from the Greek word *tome* (to cut), refers to the surgical procedure and the act of making an opening in the trachea. On the other hand, "tracheostomy," from the Greek word *stomoun* (to provide a mouth or opening), refers to the actual opening or hole in the trachea. A tracheostomy tube is the tube that is placed into that opening in the trachea.

HISTORY

The history of tracheotomy is fascinating and a knowledge of that history helps better understand the procedure today. References to making an opening in the windpipe are found in at least two of the three oldest known medical books, including the Rig Veda, a sacred Hindu book written between 2000 and 1000 BC (5). In the eighth century BC, Homer described the operation of cutting open the trachea to relieve a choking person (5). In the fourth century BC, Alexander the Great is reported to have punctured the trachea with the point of his sword to help a soldier choking on a bone lodged in his throat. Asclepiades, who practiced in Rome in the second century BC, was the first surgeon known to perform elective tracheotomies. Galen and Aretaeus both described and discussed tracheotomy in the second century AD (5,6). The procedure was further defined in the second century AD by Antyllus, who recommended that the *arteria aspera* (trachea) be divided with a transverse incision at the third or fourth ring (6). In the seventh century AD, Paul of Aegina repeatedly performed tracheotomy and recorded that one could know when the airway had been entered by the rush of air and the loss of the patient's voice (6). From that time until the 16th century, there is little in written medical history about tracheotomy.

There are frequent references to tracheotomy from the 16th century until around 1830, but most were negative, considering the procedure useless and dangerous (5). During this time period, only 28 successful tracheotomies were described in the literature (6). In 1590, Sanatorius used a trocar to perform a tracheotomy and left a cannula in place for the first time (5). In 1620, Nicholas Habicot

described what was possibly the first successful pediatric tracheotomy in a 14-year-old boy, who swallowed a cloth wrapped around 9 coins. The package of coins lodged in the esophagus and compressed the trachea, causing airway obstruction. The tracheotomy relieved the airway obstruction and the coins were pushed into the stomach, later to pass in the stool (6). Habicot also performed a tracheotomy in another young man as a means to evacuate blood from the airway, which had resulted from a penetrating wound of the larynx (5). In 1650, Theophilus Bonetus recommended the use of tracheotomy for a 7-year-old boy who had airway obstruction from aspirating a piece of bone; unfortunately, he was overruled by the boy's primary physician and the child died (5).

Heister was the first to use the term "tracheotomy". In 1839, he described the operation using a straight tube and a trocar, and suggested that it had been neglected by modern surgeons (5,6). In the early and mid-19th century, tracheotomy became commonly used as a life-saving treatment for diphtheria patients (5). Trousseau (7) reported having performed the operation on more than 200 patients with diphtheria, and saving the lives of about one quarter of them. As a result of the successful use of tracheotomy for airway obstruction in diphtheria patients, the operation became popular for other causes of airway obstruction, including croup, foreign bodies, and trauma (5). Indeed, the medical literature in the second half of the 19th century is full of articles on tracheotomy, including technique, postoperative complications, and indications (5).

Chevalier Jackson (8,9) demonstrated that when tracheotomy is performed with proper technique and postoperative care, the mortality from the procedure is quite low. He recommended using a slow and deliberate technique and avoiding a hasty operation, avoiding general anesthesia when airway obstruction is present, avoiding a "high" tracheotomy or division of the cricothyroid membrane, and dividing the thyroid isthmus (8,9). He also emphasized the importance of proper postoperative care, stating "the 'pipes,' natural and instrumental, must at all times be kept clear" (8).

Tracheotomy was also used in the early administration of general anesthesia in the late 19th century (5). However, by the early 1900s, when endotracheal intubation was popularized, the use of tracheotomy for this indication markedly decreased. In addition, in the early 20th century, immunization for diphtheria and the introduction of sulfonamides significantly decreased airway problems from upper respiratory infections (5).

In the 1930s, tracheotomy again was popularized as a useful procedure for the respiratory care of patients with poliomyelitis (5,10). The introduction of the polio vaccine (Salk vaccine) in the 1950s markedly decreased the incidence of poliomyelitis and the need for tracheotomy for this indication. As late as the 1970s, laryngotracheobronchitis and epiglottitis were common indications for tracheotomy in children, before endotracheal intubation became a popular treatment for acute airway obstruction from inflammation (11). However, vaccination against *Haemophilus influenzae* type B has contributed to significantly decreasing the rates of epiglottitis in children.

Since the 1960s and 1970s, the indications for tracheotomy in the pediatric population have shifted from its predominant use for the treatment of acute airway obstruction from infection and inflammation to the modern indications of the need for prolonged ventilation in patients with respiratory failure (e.g., from prematurity and bronchopulmonary dysplasia), the management of chronic airway obstruction, and the need for pulmonary toilet to manage excessive secretions (12–14).

INDICATIONS FOR TRACHEOTOMY

There are three main indications for tracheotomy in the pediatric population: (a) respiratory failure and anticipated need for prolonged ventilation; (b) upper airway obstruction; (c) providing access for pulmonary toilet. Some children who benefit from tracheotomy have more than one of these indications. Table 92.1 lists many of the indications for tracheotomy in children, divided into these three main categories, although there is some overlap between these categories.

A survey of 85 pediatric otolaryngologists who performed a combined total of more than 2,000 tracheotomies per year demonstrated that about 40% were performed for ventilator dependency, 30% for extrathoracic airway obstruction, 20% for neurologic dysfunction, and 10% for intrathoracic airway obstruction (15). In two separate series of patients separated by a decade, Wetmore et al. (11,13) found that prolonged intubation was the primary indication for tracheotomy in 53% of patients and airway obstruction in 38% or 39% or patients, with the remaining patients having other indications such as pulmonary toilet. In a recent series from Lyon, France, prolonged ventilator dependence was the indication for tracheotomy in 57% of children and upper airway obstruction in 43% (16). Another recent study demonstrated that 46 of 70 children (66%) who underwent tracheotomy had the procedure for prolonged mechanical ventilation (17). This study also found that children who have a tracheotomy for prolonged mechanical ventilation are likely to require a significantly longer hospital stay than children who have a tracheotomy for other reasons (17).

Many studies have demonstrated a significant change in indications for tracheotomy in the past 30 years (12,13,18,19). There has been an increase in tracheotomies for prematurity and chronic lung disease, congenital anomalies, acquired subglottic stenosis, and neuromuscular disease, and a concomitant decrease in tracheotomies for infectious diseases such as laryngotracheobronchitis (croup) and epiglottitis, as well as for short-term airway management (13,18). In one study, infants and young children were most likely to undergo tracheotomy for congenital anomalies, prematurity, lung disease, or some combination of these indications, whereas in adolescents, injury was the most common reason for tracheotomy (1).

TABLE 92.1 INDICATIONS FOR TRACHEOTOMY

Upper Airway Obstruction
- Laryngeal stenosis
  - Subglottic stenosis
  - Posterior glottic stenosis
- Tracheal stenosis
- Severe laryngomalacia
- Severe tracheomalacia
- Micrognathia
  - Macroglossia
  - Laryngeal web
  - Vocal fold paralysis
    - Hydrocephalus
    - Chiari malformation
    - Mobius syndrome
    - Other syndromes
    - Idiopathic
    - Iatrogenic
- Craniofacial syndromes
  - Pierre-Robin sequence
  - Treacher-Collins syndrome
  - Beckwith-Wiedemann syndrome
  - Other syndromes
- Lymphatic vascular malformations
- Trauma
  - Laryngeal fracture
  - Other laryngeal or tracheal injury
  - Facial injury with severe soft tissue edema
  - Trauma to recurrent laryngeal nerves
- Infectious/inflammatory
  - Epiglottitis
  - Laryngotracheobronchitis (croup)
  - Diphtheria
  - Tetanus
  - Ludwig angina
- Neoplastic
  - Laryngeal tumor
  - Tracheal tumor
  - Large tumor of oral cavity or oropharynx
  - Severe papillomatosis
  - Subglottic hemangioma
- Hypotonia secondary to neurologic or neuromuscular disorder
- Severe obstructive sleep apnea

Prolonged Intubation/Respiratory Failure
- Prematurity
- Bronchopulmonary dysplasia
- Congenital heart anomaly
- Hypoplastic lung
- Trauma
  - Traumatic brain injury
  - Pulmonary hemorrhage
  - Crushed chest
- Infectious/inflammatory
  - Pneumonia
  - Bronchiolitis
  - Meningitis
  - Encephalitis
- Neoplastic
  - Brain tumor
  - Spinal cord tumor
- Neurologic impairment
  - Hypoxic-ischemic encephalopathy
  - Myasthenia gravis
  - Guillain-Barré syndrome
  - Central respiratory impairment/central hypoventilation
- Other

Pulmonary Toilet
- Neurological impairment
  - Cerebral palsy/static encephalopathy
  - Hypoxic-ischemic encephalopathy
  - Neuromuscular disorders
  - Traumatic brain injury
  - Hypotonia
- Aspiration secondary to vocal fold paralysis
- Aspiration secondary to decreased laryngeal sensation

In children, respiratory failure and prolonged ventilator dependence are often caused by prematurity and bronchopulmonary dysplasia. In a study of 450 children who underwent tracheotomy, Wetmore et al. (13) found that bronchopulmonary dysplasia was the most common diagnosis.

Upper airway obstruction in children may be caused by craniofacial or structural abnormalities of the upper airway or by dynamic obstruction from hypotonia secondary to neurologic or neuromuscular disorders (12). Such hypotonia also can result in excess secretions or difficulty managing secretions; in these cases, tracheotomy also provides the benefit of easier access for suctioning and pulmonary toilet.

In the pediatric population, more tracheotomies are performed during the first year of life than during any other age group (12). In a series of preterm infants undergoing tracheotomy, Pereira et al. (20) found that 73% were performed for ventilator dependence, 18% for airway obstruction, and 9% for pulmonary toilet (20). Another study of tracheotomy in the preschool population found that tracheotomies are not very commonly performed in preschool-age children and the most common indication in this age group is the need for pulmonary toilet, often due to progressive neurologic disease; trauma was the second most common indication in this age group (21).

TRACHEOTOMY VERSUS ENDOTRACHEAL INTUBATION

Since the late 1970s, endotracheal intubation has replaced tracheotomy as the primary management technique for airway obstruction secondary to infectious etiologies such as laryngotracheobronchitis and epiglottitis (12,18). Anesthesiologists and pediatric intensivists have become more skilled at performing difficult intubations. For example, fiberoptic intubation has permitted some patients with

TABLE 92.2 TRACHEOTOMY VERSUS PROLONGED ENDOTRACHEAL INTUBATION

	Tracheotomy	Prolonged Intubation
Advantages	Shorter, larger tube can be placed Decreased airway dead space Less damage to larynx, including supraglottic, glottic, and subglottic regions More comfortable for the patient May allow child to be discharged from the hospital, even on a ventilator Care for the tracheostomy can be performed by trained caregivers/family who are not health care professionals	Can be performed by a variety of health care providers Does not require a surgical procedure and associated complications
Disadvantages	Requires an experienced surgeon Complications associated with tracheotomy (see Complications section) Requires a surgical procedure	Endotracheal tubes may be plugged easily Increased airway dead space More likely to cause damage to the larynx and trachea Less comfortable for the patient Care cannot be performed easily by patient/family caregivers

craniofacial disorders to have endotracheal intubation rather than a tracheotomy.

In the neonatal and pediatric intensive care units, improved management of endotracheal tubes has both decreased the complication rate from prolonged intubation and improved long-term intubation as an alternative to tracheotomy (18). In one recent 12-year series, the overall rate of tracheostomy tube placement for patients admitted to the neonatal intensive care unit was 0.7% (22). Indeed, the incidence of neonatal-acquired subglottic stenosis has significantly decreased over the past several decades (23).

Endotracheal intubation has the potential to cause injury to the glottis, subglottic region, and trachea relatively quickly, particularly if there is an improperly sized endotracheal tube, over-inflated endotracheal tube cuff, infection, or active gastroesophageal reflux. Perichondritis, infection, and active reflux can lead to delayed healing and scar formation. In adults, tracheotomy is typically recommended when there is an anticipated need for endotracheal intubation for more than 1 or 2 weeks. In infants and children, this time period can be prolonged with proper selection of endotracheal tube size, avoiding cuffed tubes or minimizing the pressure in the cuffs, and restricting movement on the tube. Newborns can tolerate longer periods of intubation (greater than 50 days) with a low risk of subglottic stenosis (24). One study suggested that children between the ages of 1 month and 18 years can also tolerate prolonged intubation well, and that with a properly managed endotracheal tube, 30 to 60 days is a reasonable time period (24). The average intubation period before tracheotomy in children was 32 days in one recent study and 43 days in another (19,25). However, there is no standard timing for tracheotomy after prolonged ventilation in children (17,24). The need for repeated intubation for a variety of reasons or multiple failed self-extubations also may be a reason for an earlier tracheotomy.

Table 92.2 provides a list of the relative advantages and disadvantages of tracheotomy versus prolonged endotracheal intubation. For children who have a relatively short need for intubation and who are not moving around, endotracheal intubation may be a better choice than tracheotomy. One advantage of endotracheal intubation is that it can be performed by many health care providers, whereas tracheotomy requires an experienced surgeon. Endotracheal intubation does not require a surgical procedure with the associated complications. However, disadvantages of endotracheal tubes include that they can become easily plugged, especially in younger children with smaller tubes, they can cause damage to the glottis and subglottis, and they are less comfortable for awake patients.

With tracheotomy, shorter, larger tubes can be placed, leading to decreased airway dead space and easier access for pulmonary toilet. There is less propensity to cause damage to the larynx, including the supraglottic, glottic, and subglottic regions. Tracheostomy tubes tend to be more comfortable for awake patients than endotracheal tubes. Children with a tracheostomy can be discharged from the hospital, even while still requiring a mechanical ventilator. In addition, care for children with a tracheostomy can be provided by trained caregivers/family members and does not necessarily require the constant presence of a health care professional.

There are a variety of techniques available to try to avoid tracheotomy in certain cases of upper airway obstruction (16). For example, some patients with isolated acute subglottic injury from endotracheal intubation can respond to balloon dilation of the airway. In selected cases of patients with recurrent croup and fixed subglottic stenosis, when this is the only airway lesion and the patient has no pulmonary compromise, a single stage laryngotracheal reconstruction

Figure 92.1 Proper positioning of the pediatric patient for a tracheotomy.

can be an alternative to tracheotomy. Some patients with Pierre Robin sequence and airway obstruction from retrognathia and glossoptosis can avoid a tracheotomy by undergoing mandibular distraction osteogenesis as a newborn. The details of these techniques to avoid tracheotomy and their appropriate indications are beyond the scope of this chapter.

TRACHEOTOMY TECHNIQUE

With the exception of a few life-threatening emergencies, tracheotomy in children should be performed in the controlled setting of the operating room under general anesthesia. When possible, the procedure should be performed with the patient intubated with an endotracheal tube to control the airway. If there is significant upper airway obstruction and endotracheal intubation is not possible but a rigid ventilating bronchoscope can be inserted, the procedure can also be performed over the bronchoscope. A laryngeal mask airway (LMA) can also be used when it is not possible to perform endotracheal intubation and a rigid bronchoscope cannot be passed or is not available. In children, awake tracheotomies without a controlled airway should be reserved for the few life-threatening situations in which endotracheal intubation or insertion of a rigid bronchoscope or LMA is not possible. Percutaneous tracheotomy is generally not recommended in children.

The patient is placed supine on the operating table with a shoulder roll to extend the neck (Fig. 92.1). In children with short necks or significant submental fat, tape can be used to help keep the submental pannus out of the way and to hold the head in position. The neck is carefully palpated and the level of the cricoid cartilage, thyroid notch, and sternal notch are marked (Fig. 92.2). The infant larynx is located higher in the neck than in older children and adults, the thyroid cartilage is broader, and the cricoid cartilage is often the most prominent palpable structure. The skin incision is marked between the level of the sternal notch and cricoid cartilage (Fig. 92.3). The skin can be infiltrated with local anesthesia with epinephrine. The neck is then prepared and draped, although the face is often left uncovered in order to provide access to the endotracheal tube by the anesthesiologist.

Either a horizontal or vertical skin incision can be made. Excessive subcutaneous fat deep in the incision can be removed using electrocautery (Fig. 92.4). The platysma fascia is divided. The strap muscles are then divided vertically and retracted (Figs. 92.5 and 92.6). The thyroid isthmus can be retracted superiorly or inferiorly, or divided (Fig. 92.7). If the thyroid isthmus is sitting over the area where the incision in the trachea should be made, the isthmus should be divided with electrocautery and ligated. The trachea is palpated often during the procedure to ensure

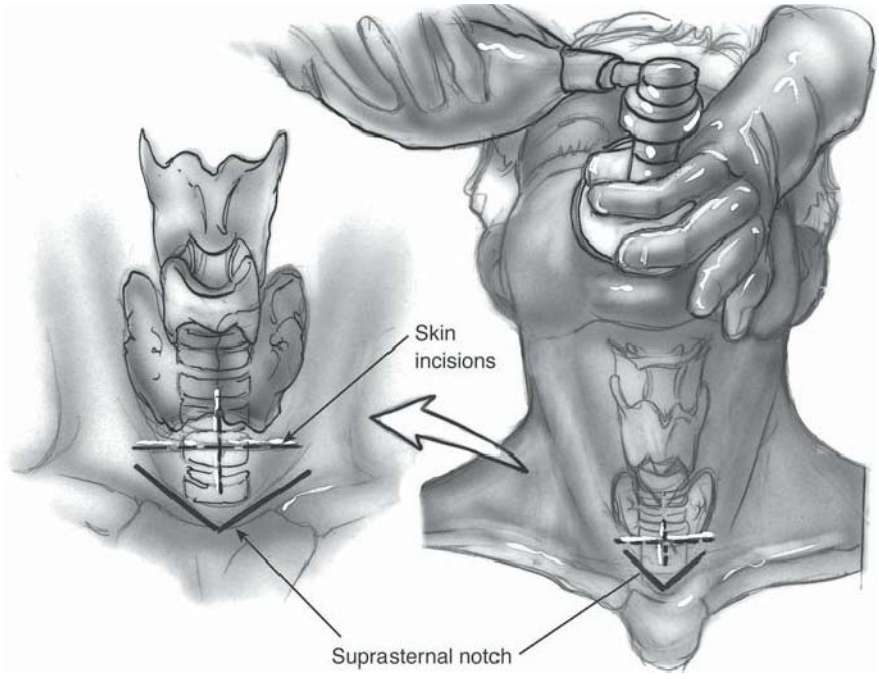

Figure 92.2 Anatomy of the neck and skin incision, which can either be horizontal or vertical.

Figure 92.3 Proper positioning of the pediatric patient for a tracheotomy. The patient is placed supine on the operating table with a shoulder roll to extend the neck. Tape is used to keep the submental fat out of the way and help hold the head in position. The level of the cricoid cartilage, sternal notch, and skin incision are marked.

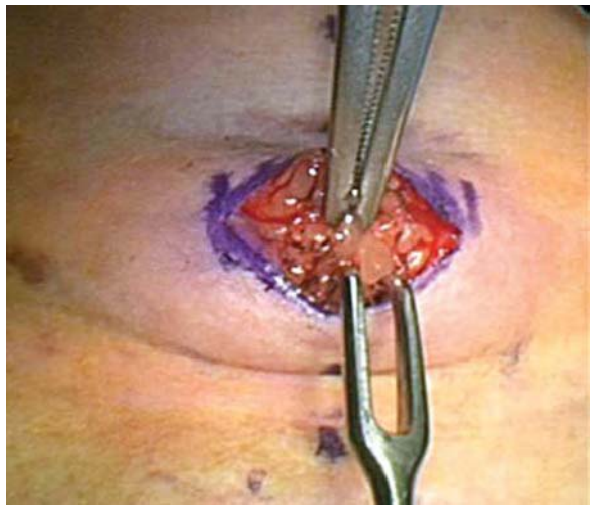

Figure 92.4 Removal of excess subcutaneous fat deep to the skin incision.

that the approach to the trachea remains in the midline (Fig. 92.8). The trachea in children is more pliable and has more lateral mobility than in adults; so it is important to be sure that dissection remains in the midline with the trachea centered in the surgical field. Excessive lateral dissection should be avoided to help minimize subcutaneous air and decrease chance of injury to the dome of the pleura or recurrent laryngeal nerves. When using electrocautery during tracheotomy, the fraction of inspired oxygen (FiO_2) should be kept below 30% to help prevent a surgical fire.

In infants and small children, a vertical incision in the trachea may be preferred (Fig. 92.9). It has been suggested that the vertical incision may decrease the incidence of suprastomal collapse and tracheal stenosis (18). In older children and adolescents, either a vertical incision in the trachea or an inferiorly based flap (Bjork flap) can be employed (11,26,27). Waki et al. (27) have advocated an inferiorly based tracheal flap for all pediatric patients, including infants. However, one survey revealed that most pediatric otolaryngologists (75%) prefer a vertical incision (15).

The vertical incision in the trachea is typically made through rings 2 and 3. Retention sutures (stay sutures) should be placed in a paramedian position on each side of the incision prior to making the incision to help retract the opening in the trachea intraoperatively and facilitate replacement of the tube in case of accidental decannulation in the early postoperative period, prior to the establishment of a mature tracheostomy stoma tract (Figs. 92.10 and 92.11) (15). The importance of these retention sutures cannot be overemphasized, as they can be life saving.

Figure 92.11 The vertical incision in the trachea is typically made through rings 2 and 3. Stay sutures are placed in a paramedian position on each side of the incision.

Figure 92.12 Tracheostomy tube is in good position with stay sutures present.

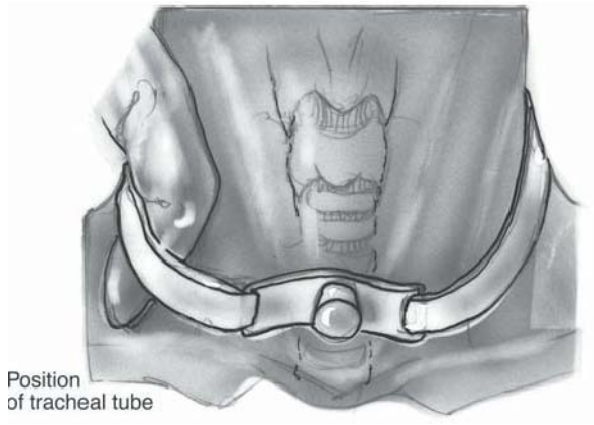

Figure 92.14 Proper position of the tracheostomy tube.

The endotracheal tube is slowly withdrawn to allow for insertion of the tracheostomy tube. However, the tip of the endotracheal tube should remain just below the glottis and should not be completely removed until it is confirmed that the tracheostomy tube is in good position and secure (Fig. 92.12) (11).

Once the tracheostomy tube is in good position and it is confirmed that the patient can be ventilated adequately through the tube, the surgical site is again inspected to ensure that there is good hemostasis. The endotracheal tube can then be removed completely. DuoDERM (ConvaTec Professional Services, Skillman, NJ) can be applied to the neck to help prevent irritation from the tracheostomy tube ties (Fig. 92.13). Cotton tracheostomy tube ties are then placed and tied to secure the tracheostomy tube (Fig. 92.14). In children, it is recommended not to suture the flange of the tracheostomy tube to the skin because children often have shorter tracheostomy tubes, which may be more likely to be displaced from the trachea. If this accidental displacement occurs and the tracheostomy tube is sitting in a false passage, sutured flanges can delay rapid removal of the tracheostomy tube and replacement into proper position.

The stay sutures are then labeled with adhesive tape ("left" and "right") and taped to the chest wall (Fig. 92.15). A flexible tracheoscopy through the tracheostomy tube can be performed to confirm that the tracheostomy tube is the correct size and that the tip of the tracheostomy tube is sitting in good position with respect to the carina. For patients who have had a prolonged intubation, a direct laryngoscopy and rigid tracheoscopy can then be performed to assess for possible injury or inflammation in the area of the true vocal folds, subglottis, and suprastomal trachea.

Pediatric tracheotomy can be performed with or without maturation of the stoma. Maturation of the stoma involves suturing the skin edges to the tracheal cartilage (Fig. 92.16) (28). In a survey of pediatric otolaryngologists performing tracheotomy, 41% routinely matured the

stoma (15). Techniques for stomal maturation include suturing four quadrant or vertical skin flaps to tracheal cartilage, suturing an inferiorly-based cartilage flap to the skin (Bjork flap), and a starplasty technique, in which four skin flaps are intercalated among four tracheal cartilage flaps based on Z-plasty principles (26,29,30). One study suggested that maturation of the stoma may decrease the morbidity of early accidental decannulation while leading to no increase in the rate of tracheocutaneous fistula formation (31). These authors felt that tracheostomy tubes in children with matured stomas were easier to replace in the event of accidental decannulation (31). Another study found that the rates of tracheostomy-related complications were similar between matured and nonmatured stomas, including the rates of development of granulation tissue and tracheocutaneous fistulae (28).

The choice of tracheostomy tube depends on the age and size of the child and his or her respiratory status. Patients that require positive pressure ventilation require either a more snug-fitting tracheostomy tube or a cuffed tube to help prevent too large an air leak around the tube, which could make ventilation difficult. Even when there is the need for positive pressure ventilation, smaller children often can be ventilated with an uncuffed tube, which prevents the potential problems associated with a cuff, including overinflation, mucosal injury, and subsequent tracheal stenosis. For children who do not require a ventilator, a smaller tracheostomy tube can be placed, which has the advantage of causing less pressure on the tracheal walls and permitting airflow around the tracheostomy tube to allow for phonation and the use of a speaking valve.

POSTOPERATIVE CARE

Pediatric patients are typically kept in the intensive care unit or a special airway observation unit for at least the first 5-to-7 days after a tracheotomy until the first tracheostomy tube change is performed. By that time, it is less likely that the tube will be placed into a false passage, as the stoma tract is more established. If needed, the patient should be kept sedated and/or restrained until the first tracheostomy tube change in order to help prevent accidental decannulation. The ventilator typically is managed by the pediatric intensivists. Suctioning through the tracheostomy tube should be performed every 1 to 2 hours for the first few days and then, as needed, for secretion control and to help prevent mucus plugging. Care must be taken that the ventilator circuit is not causing traction on the tracheostomy tube, which could contribute to accidental decannulation or erosion of the stoma.

The first tracheostomy tube change, after 5 to 7 days, should be performed by an otolaryngologist or another physician experienced in tracheostomy care in order to determine that the stoma tract has healed well enough to allow nurses, respiratory therapists, and parents to perform future tracheostomy tube changes safely. One author has advocated that the tracheostomy tube can be changed safely as early as 3 or 4 days after surgery but it is more common to wait for 5-to-7 days (32). The tracheostomy tube ties placed at the time of the surgical procedure are often cotton and tied in a knot to help prevent them from loosening in the immediate postoperative period. After the first tracheostomy tube change, the tracheostomy tube ties can also be changed to softer Velcro ties. Also after 5-to-7 days, once a safe tracheostomy stoma tract is established, the stay sutures (retention sutures) can be removed.

A chest radiograph should be ordered in the immediate postoperative period to confirm proper tracheostomy tube position and length with respect to the carina and to rule out pneumothorax or pneumomediastinum (33). As mentioned previously, many otolaryngologists performing tracheotomies in children also perform a flexible tracheoscopy on the operating room table after the tracheostomy tube is inserted to establish that the tube is of correct size with respect to the trachea and carina (33).

Children not on a ventilator are usually able to start oral feedings on postoperative day one. If there is concern for aspiration or dysphagia, an initial bedside clinical swallowing evaluation should be performed by a speech pathologist prior to starting feeding. If there is persistent concern for aspiration, consideration should be given to obtaining an instrumental swallowing assessment such as a videofluoroscopic swallowing study (modified barium swallow study) or a fiberoptic endoscopic evaluation of swallowing (FEES) prior to starting an oral diet.

After the first tracheostomy tube change, the patient's home caregivers then begin to learn routine tracheostomy care, how to manage problems such as mucus plugging and accidental decannulation, and cardiopulmonary resuscitation. Teaching can be performed by physicians, nurse educators, and respiratory therapists experienced in tracheostomy care. The topics include tracheostomy tube-changing technique, frequency of tube changing, suctioning technique and frequency, wound care, recognition of infection and respiratory distress, emergency procedures, and acceptable activities (33,34). Many pediatric otolaryngologists use a tracheostomy management team including

physicians, clinical nurse specialists, respiratory therapists, and other specialists to help with tracheostomy teaching and care (15).

Patients with a tracheostomy tube should not be discharged from the hospital until it is determined that their home caregivers have had adequate training and are comfortable managing the tracheostomy. Proper education and home care help prevent complications after discharge from the hospital (35). In a survey of pediatric otolaryngologists performing tracheotomy, the average time parents were trained prior to a child's discharge from the hospital was 9 days (15). One study found that the average hospital length of stay for children undergoing a tracheotomy was 50.2 days (1).

It is critical that an adult with proper training be present at all times with a child who has a tracheostomy. Home skilled nursing care for children with tracheostomy tubes can be very helpful in aiding parents and preventing complications. Tracheostomy care manuals have been prepared by many children's hospitals and are also available commercially. Proper equipment should be available in the home, including oxygen, suction, suction catheters, saline bullets, apnea monitor, pulse oximetry, and an Ambu bag. The patient should be discharged home with spare tracheostomy tubes of the same size and one size smaller, the latter to be used in the event of an accidental decannulation or tracheostomy tube change in which the original size tube cannot be replaced. Tracheostomy tube changes should be performed on a weekly basis. The electric company, telephone company, emergency services, and local police should be made aware that there is a child in the home with a tracheostomy. It is important that the electricity and telephone service to the home be maintained.

After discharge from the hospital, children who have a tracheostomy must follow up routinely with the otolaryngologist who performed the tracheotomy as well as with their pediatrician. In larger tertiary-care children's hospitals, the trend is for tracheostomy patients to be followed in a multidisciplinary airway center, which may include otolaryngologists, pulmonologists, speech pathologists, respiratory therapists, and other health care providers who can offer different areas of expertise to help manage these often complex patients. Most otolaryngologists perform routine elective interval airway endoscopy in the operating room (3-to-6 month intervals) on all pediatric patients with tracheostomy tubes and feel that it may help prevent complications (35,36). Such endoscopy would include a flexible fiberoptic tracheoscopy, direct laryngoscopy, rigid bronchoscopy, tracheostomy tube change, and possible removal of obstructing suprastomal granulation tissue, if present. Some other otolaryngologists only take patients to the operating room for endoscopy when they present to the office with tracheostomy-related problems. Children with long-term tracheostomies need to have their airways evaluated periodically as they grow to ensure that the tracheostomy tube is the correct size and in the correct position.

COMPLICATIONS OF TRACHEOTOMY

Tracheotomy in children has been associated with a higher rate of complications than adults (11,31). Complications of pediatric tracheotomy can be divided into intraoperative complications, early postoperative complications, and late postoperative complicawtions. Table 92.3 lists the complications of pediatric tracheotomy, divided into these three categories. Early postoperative complications are typically considered to occur within the first week after surgery and late complications occur after 7 days. The overall rates of early complications have been reported to be from 5.0% to 28.0% and late complication rates have been reported to be as high as 63.5%, with as many as 43.0% of these late complications considered to be serious (2,13,14,19,25,28,35–37).

The most common intraoperative complication is hemorrhage. Meticulous dissection technique and control

TABLE 92.3 COMPLICATIONS PEDIATRIC TRACHEOTOMY

Intraoperative Complications
- Bleeding
- Loss of airway or inability to ventilate
- Subcutaneous emphysema
- Pneumomediastinum
- Pneumothorax
- Esophageal injury
- Creation of false passage
- Recurrent laryngeal nerve injury
- Cardiopulmonary arrest, death

Early Postoperative Complications (<7 days)
- Accidental decannulation
- Tracheostomy tube occlusion
- Bleeding
- Subcutaneous emphysema
- Pneumomediastinum
- Pneumothorax
- Creation of false passage
- Stoma/wound breakdown or cellulitis
- Neck skin erosion from tracheostomy tube ties
- Tracheitis

Late Postoperative Complications (>7 days)
- Accidental decannulation
- Tracheostomy tube occlusion
- Peristomal granulation tissue
- Suprastomal granulation tissue
- Stoma/wound breakdown or cellulitis
- Neck skin erosion from tracheostomy tube ties
- Tracheostomy stomal stenosis
- Suprastomal cartilaginous collapse
- Subglottic stenosis
- Tracheomalacia
- Tracheitis
- Tracheal stenosis
- Tracheal granulation tissue
- Airway hemorrhage
- Tracheo-innominate artery fistula
- Persistent tracheocutaneous fistula after decannulation

of bleeding vessels with electrocautery and ties can help prevent intraoperative hemorrhage. It is also recommended that if the thyroid isthmus is divided, it be carefully suture ligated. The possibility of a coagulation abnormality must be considered in any child with excessive bleeding during or immediately after a tracheotomy procedure.

Other intraoperative complications include subcutaneous emphysema, pneumomediastinum, pneumothorax, esophageal injury, recurrent laryngeal nerve injury, creation of a false passage, difficulty ventilating, and cardiopulmonary arrest (14,18,35). Interstitial air such as subcutaneous emphysema often can be prevented by avoiding suturing the edges of the skin incision closed and by confining the dissection to the midline of the trachea without dissecting too far laterally. Pneumomediastinum and pneumothorax can develop from a progression of subcutaneous emphysema or from injury to the dome of the pleura during the tracheotomy procedure. In infants, the apex of the lung can extend into the root of the neck, above the clavicle. Rupture of alveoli caused by excessive coughing in the immediate postoperative period or increased negative intrathoracic pressure also can lead to pneumomediastinum and pneumothorax. Subcutaneous emphysema and pneumomediastinum typically will resolve on their own and can be managed expectantly. Small pneumothoraces can be observed but larger pneumothoraces may require a thoracostomy tube.

Esophageal injury and tracheoesophageal fistula formation also can occur intraoperatively, and usually can be prevented by avoiding making the anterior tracheal wall incision too deep which could cause damage to the posterior tracheal wall (membranous trachea), avoiding forcing the tracheostomy tube roughly into the trachea, and removing esophageal feeding tubes for the procedure. Injury to the recurrent laryngeal nerves can be prevented by keeping dissection close to the midline.

There is some overlap between intraoperative and early postoperative complications, which can also include bleeding, subcutaneous emphysema, pneumomediastinum, and pneumothorax (18).

Certain complications, such as accidental decannulation (3.3% to 11.6%) and tracheostomy tube occlusion (1.8% to 9.9%) can occur in the early or late periods (13,28,35,36,38). Both tracheostomy tube plugging and accidental decannulation are amongst the most common causes of tracheostomy-related morbidity and mortality (12,18,33,38,39). The rates of accidental decannulation are probably higher than reported in the literature, as many episodes of accidental decannulation are not documented unless there is significant morbidity or a requirement to return to the operating room for a stoma revision as a result. Morbidity and mortality from accidental decannulation can be minimized by carefully securing the tracheostomy tube with ties, utilizing stay sutures, and closely observing patients in the intensive care unit or a special airway observation unit until the first tracheostomy tube change. As stated above, some otolaryngologists also feel that maturing the stoma decreases the morbidity from accidental decannulation but this issue is somewhat controversial (31).

Tracheostomy tube obstruction/plugging tends to occur more frequently in premature infants and newborns compared with children older than 1 year (18). This finding likely is due to the smaller diameter tracheostomy tubes used in infants as well as the fact that many premature infants with tracheostomy tubes have bronchopulmonary dysplasia, which can lead to thicker bronchial secretions (18). Appropriate tracheostomy tube care can help prevent tracheostomy tube obstruction. Such care includes frequent suctioning, use of saline with suctioning, and humidifying the inspired air or oxygen. Changing the tracheostomy tube at a proper frequency (ideally every week) can also help prevent mucus plugging.

Stoma/wound breakdown or stoma cellulitis also can occur in the early or late periods. In one study, the rate of wound complications after tracheotomy was 29% (40). Patients less than age 1 year had a higher wound complication rate than older patients (40). It is important to minimize pressure from the ventilator circuit on the tracheostomy tube. The stoma site should be kept as clean and dry as possible to help prevent infection and wound breakdown around the stoma. Barrier protection between the flanges of the tracheostomy tube and the skin can also help prevent early tracheotomy wound breakdown (40). Tracheostomy tube ties that are too tight or moist can lead to skin ulceration. Aggressive local wound care can help prevent early stoma wound breakdown from progressing to more severe wounds. Triple antibiotic ointment can be used to treat mild infection and granulation tissue around the stoma.

Two other common late complications and their reported incidences include the development of peristomal granulation tissue (6.1% to 26.7%) and suprastomal granulation tissue (38.7% to 48.8%) (12,13,28,36,38). Granulation tissue in the peristomal or suprastomal area is quite common and can be harmless (19). However, such granulation tissue can also lead to bleeding, difficulty with tracheostomy tube changes, and suprastomal airway obstruction (Fig. 92.17) (18). Peristomal granulation tissue can be treated with topical triple antibiotic ointment or it can be cauterized with silver nitrate. Severe peristomal granulation tissue can also contribute to the development of tracheostomy stomal stenosis (Fig. 92.18). When such stomal stenosis develops to the extent that tracheostomy tube changes become difficult, a formal stoma revision may be necessary. Obstructing suprastomal granulation tissue can be removed with a variety of techniques, including open excision, endoscopic excision with optical forceps, or excision through the stoma with a small hook and tenotomy scissors, sphenoid punch, or microdebrider (41,42).

Granulomas also can develop at the tip of the tracheostomy tube and can be life threatening in this location by obstructing the tube. Such granulomas can be detected during interval surveillance endoscopy, either performed

Figure 92.17 Endoscopic view of a totally obstructing suprastomal granuloma.

in the office via flexible tracheoscopy or in the operating room during a complete airway endoscopy. When such granulation tissue is detected, changing the tube length, shape, or material may be helpful. Obstructing granulation tissue can be removed endoscopically with a variety of techniques, including optical forceps or laser. Topical steroids applied through the tracheostomy tube also can help decrease the severity of tracheal granulation tissue.

Suprastomal cartilaginous collapse is another late complication. Mild suprastomal collapse is quite common and is not typically a problem. However, more severe suprastomal collapse can lead to significant airway obstruction and interfere with successful decannulation. This complication may be responsible for decannulation failure in 2.4% to 18% of children (43). There are a variety of techniques to manage severe suprastomal cartilaginous collapse, including endoscopic excision with a laser, partial excision of the collapsed segment through the stoma with Kerrison rongeurs, placement of tracheal suspension sutures, and laryngotracheal reconstruction with anterior rib cartilage grafting (43,44).

Figure 92.18 Large peristomal granuloma causing tracheostomy stomal stenosis and difficulty with tracheostomy tube changes.

Another serious late complication of tracheotomy is the development of tracheal stenosis that can develop from pressure from the distal end or cuff of the tracheostomy tube as well as from local infection and inflammation (18). In addition, tracheomalacia can develop as a long-term complication of tracheotomy, particularly involving the suprastomal portion of the trachea.

The incidence of subglottic stenosis as a late complication of tracheotomy has decreased since Chevalier Jackson (8) emphasized the dangers of performing a tracheotomy too "high" in 1921. Subglottic stenosis can be caused by inserting the tracheostomy tube too close to the cricoid cartilage or through the cricoid cartilage. However, subglottic stenosis more frequently occurs as a result of subglottic injury from prolonged endotracheal intubation prior to the tracheotomy being performed and is not considered a complication of the tracheotomy in these cases. Subglottic stenosis as a result of the tracheotomy itself can typically be avoided by careful dissection and placing the incision in the trachea at the correct level.

Development of a tracheo-innominate artery fistula is the most dreaded serious late complication of tracheotomy. Although rare, this complication represents a true emergency and has a high mortality rate. The innominate artery typically comes off of the aorta and crosses the trachea either deep to the sternum or in the inferior portion of the neck in the case of a high-riding innominate artery. Pressure on the anterior tracheal wall from the tracheostomy tube tip or cuff can cause erosion, predisposing to tracheo-innominate artery fistula formation. Although most bleeding from a tracheostomy is caused by granulation tissue, tracheitis, or suction trauma, the possibility of a tracheo-innominate artery fistula must be considered and all children with bleeding from their tracheostomy must be evaluated. When there is bleeding granulation tissue noted on the anterior tracheal wall, there is a high possibility of the presence of a tracheo-innominate artery fistula. Exploration should be performed in the operating room with a pediatric general or cardiothoracic surgeon immediately available. A cuffed endotracheal tube or tracheostomy tube can be placed through the stoma to attempt to tamponade severe bleeding. Placing a finger through the stoma with endotracheal tube intubation from above also may be helpful. Definitive management requires a sternotomy and division/ligation of the innominate artery.

Some series also include tracheitis as an early and late complication of tracheotomy, with an incidence of 8.3% to 48.8% (28,35,36). However, many others do not include tracheitis as a complication, but rather a sequela of having a tracheostomy tube, and its incidence may be underreported. Tracheitis can be treated with nebulized tobramycin or with culture-directed oral or intravenous antibiotics, depending on the severity of the infection.

One study suggested that children with tracheostomy tubes are more likely to have a history of constipation and to take medications for constipation, possibly because the tracheostomy tube prevents the development of adequate subglottic and tracheal pressure during the Valsalva maneuver, which may impair the ability to defecate (45). This study was unable to prove a causal relationship between tracheostomy and constipation, however, because many of the patients with tracheotomy also had neurodevelopmental impairment, which can contribute to constipation (45).

The rate of persistent tracheocutaneous fistula after decannulation is between 2.5% and 37.1% (12,13,28,36,38,46). Persistent tracheocutaneous fistulae may be more likely in children who have a tracheostomy for longer periods of time (12,19). A few studies have found that there was no increase in the rate of tracheocutaneous fistula formation in stomas that have been matured compared with those that have not been matured (28,31). On the other hand, there is a higher rate of tracheocutaneous fistula formation after decannulation when the starplasty technique is used for stoma maturation (30). Most authors recommend waiting 6 to 12 months after decannulation to perform closure of a persistent tracheocutaneous fistula (46). Occasionally, a persistent tracheocutaneous fistula can occur because the airway remains partially obstructed at some level. In these cases, a child may depend on the persistent fistula for respiration. This possibility must be ruled out prior to performing closure of a persistent tracheocutaneous fistula.

Younger patients (less than 1 year) in general have higher complication rates than older patients (13,18,19,28). Colman et al. (28) found that younger patients had a higher rate of suprastomal granulation tissue, tracheitis, persistent tracheocutaneous fistulae, and need for additional surgical procedures for a tracheostomy-related complication. Parrilla et al. (19) also found a higher complication rate in children less than age 1 year (47.4%), compared with children above age 1 year (26.3%). The higher complication rate in younger children is likely due to the narrower diameter and increased pliability of the trachea. Furthermore, children less than 1 year of age who undergo tracheotomy are more likely to have bronchopulmonary dysplasia and abundant, viscous tracheal secretions, increasing their risk of such complications as mucus plugging (19).

Children with a tracheostomy are at risk for frequent hospitalizations for several reasons, including for their primary disease, for respiratory infections such as pneumonia and tracheitis, and for other tracheostomy-related complications (2,17). One study reported that 11% of children required at least four hospitalizations within 6 months of their tracheotomy (17). In another multi-institutional study, 52% of children less than age 1 year at the time of their tracheotomy were readmitted to the hospital within 30 days of discharge (2).

The tracheostomy-related mortality rate in the literature ranges from 0% to 8%, although more recent studies report mortality rates on the lower end of that range (11–13,25,47). There has been a trend toward decreased tracheostomy-related deaths over the past few decades, likely secondary to improved care and monitoring, both in the hospital and at home (12,14). The overall mortality in children who undergo a tracheotomy is as high as 13% to 40%, but the deaths are usually related to the underlying disease process and not the tracheotomy itself (11,12,18,19,36). One study found that children who received their tracheotomy procedure at children's hospitals had lower mortality rates than children who received their tracheotomy at non-children's hospitals. This same study also found that hospitals performing larger volumes of pediatric tracheotomies had lower mortality rates (1). Children with upper airway obstruction as the indication for their tracheotomy tend to have a lower mortality rate than children with chronic lung disease, neurologic impairment, or both (2).

TRACHEOSTOMY TUBES

There are several brands of pediatric tracheostomy tubes available, including Shiley (Covidien-Nellcor, Boulder, CO), Bivona (Smiths Medical, Dublin, OH), Portex (Smiths Medical, Dublin, OH), and Tracoe (Boston Medical Products, Westborough, MA). These tracheostomy tubes are available in different widths, lengths, materials (polyvinyl chloride or silicone), and with or without a cuff. There are also metal pediatric tracheostomy tubes available (Jackson and Holinger tubes), although they are not frequently used and are often reserved for special situations, such as for certain airway reconstruction procedures. The size designations of pediatric tracheostomy tubes are based on the inner diameter of the tubes in millimeters. Neonatal tracheostomy tubes have similar inner and outer diameters to comparable size pediatric tracheostomy tubes but have a shorter length (Fig. 92.19). In contrast to adult tracheostomy tubes, pediatric tracheostomy tubes have a relatively small inner

Figure 92.19 Neonatal tracheostomy tubes have similar inner and outer diameters to comparable size pediatric tracheostomy tubes but have a shorter length. diameter, making inner cannulas impractical. Therefore, thoroughly cleaning the tracheostomy tube requires removing the entire tube and replacing it with a new one (34). Most pediatric tracheostomy tubes are uncuffed. Cuffed pediatric tracheostomy tubes are available, but are typically reserved for ventilated patients requiring higher airway pressures. The external connector for almost all pediatric tracheostomy tubes is universally the same size so that it can be attached to the same ventilator circuits, speaking valves, and artificial noses. The shafts of some tracheostomy tubes have wire reinforcement, which can interfere with some radiologic imaging. For example, such wire-reinforced tracheostomy tubes would prevent patients with those types of tubes from having an MRI with the tube in place.

For patients that require intermittent ventilation, Bivona makes a tight-to-shaft (TTS) cuffed tube, in which the cuff is designed to deflate very close to the shaft of the tube with a low profile to minimize contact with the tracheal walls when not in use (Fig. 92.20). Bivona FlexTend tracheostomy tubes have an extension anterior to the flange that can prevent children with excessive cervical/submental fat from occluding the lumen of the tube. Bivona also has a Hyperflex tracheostomy tube that is made of a soft wire-reinforced silicone (Fig. 92.21). This tube is designed to conform to the shape of the airway and can be very useful when the airway is tortuous, such as in patients with severe scoliosis.

DECANNULATION

There has been a trend over the past few decades of fewer tracheotomies overall and lower rates of decannulation, as fewer tracheotomies are being performed for infectious indications and a larger percentage are being performed for chronic lung disease and other chronic disorders (12). The underlying indication for the tracheotomy influences the chance for successful decannulation. In one study, patients with craniofacial abnormalities had a 63% chance of successful decannulation, patients with prolonged intubation had a 47% chance of successful decannulation, and patients with neurologic impairment only had a 12.5% chance of successful decannulation (12). Berry et al. (2) found that children with neurologic impairment had a lower rate of successful decannulation and a higher mortality rate than those without neurologic impairment.

In a study of children who underwent tracheotomy in the first year of life, 36.3% of term infants and 30.6% of preterm infants were decannulated successfully (14). The average length of tracheostomy use prior to successful decannulation was 458 days for term infants and 736 days for preterm infants (14). In a series of 181 children undergoing tracheotomy, Tantinikorn et al. (36) found that 64.1% were able to be decannulated successfully. In another study, successful decannulation was achieved in 62% of surviving children who underwent a tracheotomy while in the neonatal intensive care unit (22). Improvements and advances in the management of airway obstruction from subglottic stenosis and craniofacial abnormalities have improved decannulation rates in children with these problems.

For decannulation to be successful, there must be adequate improvement or resolution of the original problem that led to the requirement for a tracheotomy, whether it be respiratory failure and prolonged ventilation, upper airway obstruction, or the need for access for pulmonary toilet (48). The decision to proceed with decannulation is often multidisciplinary, and involves the patient's pediatrician, otolaryngologist, pulmonologist, gastroenterologist, and neurologist (49). Prior to decannulation, an endoscopic evaluation of the airway, including flexible fiberoptic laryngoscopy, direct laryngoscopy, and rigid bronchoscopy, should be performed to make sure that there is no supraglottic obstruction from granulation tissue or cartilaginous collapse, to assess vocal fold function, and to determine that there is no other site of airway obstruction that would

prevent successful decannulation (49). The tracheostomy tube is then downsized so that there is room in the airway to breathe around the tube while it is plugged. The tracheostomy tube is then plugged under supervision to determine whether the patient can breathe easily through the larynx and upper airway. Tracheostomy tube-plugging trials can occur during the daytime while the child is at home or out of the hospital. If the child does well with the tracheostomy tube capped during the daytime, he or she is typically admitted to a monitored bed in the hospital for a trial of nighttime capping of the tracheostomy tube prior to decannulation. At our institution, these nighttime capping trials are performed in the pediatric intensive care unit. If this nighttime capping is tolerated, the patient is then decannulated and observed for another night or two in a monitored setting prior to discharge. Once the tube is removed, a mild-pressure dressing is applied to the stoma area.

If there is concern for significant upper airway obstruction, dynamic airway collapse, or obstructive sleep apnea, a polysomnogram can be performed with the tracheostomy tube plugged prior to decannulation (50). In small infants, it may not be possible to downsize the tracheostomy tube to a small enough size to allow for a capping trial, as even the smallest tubes can fill the trachea completely. In these cases, the tracheostomy tube may occasionally be removed without a capping trial. A few otolaryngologists have advocated the use of fenestrated tubes as part of the decannulation process in children (51). However, fenestrated tracheostomy tubes are not generally recommended as part of the decannulation process in the pediatric population, as the fenestration can create significant irritation to the tracheal mucosa and promote granulation tissue formation.

COMMUNICATION CONCERNS

Children with tracheostomy tubes can have a delay in speech acquisition and decreased receptive and expressive language skills (52–54). There is a higher risk for communication disorders in children with tracheostomy tubes who already have neurodevelopmental impairment (15,53). Indeed, children with tracheostomy tubes can be significantly limited by their lack of voice (4). One study suggested that achieving the earliest decannulation possible can improve the chance of normal speech and language development (53).

It is helpful for children with tracheostomy tubes to be evaluated by a speech pathologist, both to assess swallowing function and to address communication issues. In patients who can tolerate them, speaking valves (e.g., Passy-Muir valves) can help with both verbal communication and swallowing (11,34). Contraindications to speaking valves include significant laryngeal stenosis or other forms of airway obstruction that would prevent adequate exhalation and severe neurologic dysfunction. Speech therapy for children with tracheostomy tubes can improve communication skills.

Many children with tracheotomies are able to attend school (15). Children with a tracheostomy should be allowed to have as normal a childhood as possible. A developmentally normal child who has a tracheostomy tube should not be placed in a learning situation designed for children with learning disabilities, such as special education classes.

SWALLOWING

Although tracheostomy tubes do provide easy access for pulmonary toilet, they can impair swallowing function. The tracheostomy tube can partially tether the laryngotracheal complex and impair laryngeal elevation during swallowing (55,56). An open tracheostomy tube can also reduce cough effectiveness as a protective mechanism from aspiration (55). The tracheostomy tube may cause a relative esophageal obstruction, particularly tubes that have a cuff. Furthermore, there is a blunting of the laryngeal adductor reflex in patients with a tracheostomy, which can impair airway protection during swallowing (55). In addition, an open tracheostomy tube also prevents the buildup of subglottic pressure that normally occurs during the physiologic swallow. Gross and others have demonstrated that patients with tracheostomy tubes that utilize a speaking valve such as a Passy-Muir valve are able to generate higher subglottic pressure and may be less likely to exhibit aspiration or deep penetration (55,56). Children with tracheostomy tubes should have their swallowing assessed by a speech pathologist. For patients who can tolerate them, speaking valves may not only help with communication, but also with swallowing function.

SUMMARY

The indications for tracheotomy in children have changed over the past several decades. The most common indication for tracheotomy in the pediatric population is currently respiratory failure and prolonged intubation, followed by upper airway obstruction and the need for pulmonary toilet. In general, children with tracheotomies have become more complex, as there has been a decrease in the use of tracheotomy for acute airway management and infectious diseases and an increase in tracheotomy for chronic lung disease, congenital anomalies, and neuromuscular disorders. For similar reasons, there has been a trend toward lower rates of decannulation, as the underlying reason for the tracheotomy influences the chance for successful decannulation. Children can tolerate longer periods of endotracheal intubation than adults but there is no standard timing for tracheotomy after prolonged ventilation in children. Meticulous surgical technique and appropriate postoperative care can help prevent tracheotomy complications, both intraoperatively and in the postoperative period.

Patients with tracheostomy tubes are often complex and may benefit from management by a multidisciplinary

team, including otolaryngologists, pulmonologists, speech pathologists, and respiratory therapists. Proper education and home care can help keep children with tracheostomy tubes safe and avert complications after discharge from the hospital. Tracheostomy tubes are available in a broad range of sizes, materials, and types, and it is important to select the appropriate tracheostomy tube for each child. Children who have a tracheostomy can have both impaired communication skills and abnormal swallowing function as a result of their tracheostomy. It is important to involve speech pathologists in the care of children with tracheostomy tubes to help address both of these issues. When possible, children with tracheostomy tubes should be encouraged to attend school and participate in activities in order to have as normal a childhood as possible.

HIGHLIGHTS

- Children with tracheostomies utilize a great deal of health care resources.
- There is significant emotional, social, and economic burden on caregivers taking care of children with tracheostomy tubes.
- Although the terms "tracheotomy" and "tracheostomy" have been used interchangeably in the past, "tracheotomy" refers to the surgical procedure and the act of making an opening in the trachea and "tracheostomy" refers to the actual opening or hole in the trachea.
- The history of tracheotomy dates back several thousand years and its popularity as a procedure has been influenced by various diseases and their treatment developments (such as diphtheria, poliomyelitis, and epiglottitis).
- The most common indication for tracheotomy in the pediatric population currently is respiratory failure and ventilator dependence followed by upper airway obstruction and the need for pulmonary toilet.
- In general, infants and children can tolerate longer periods of endotracheal intubation than adults; however, there is no standard timing for tracheotomy after prolonged ventilation in children.
- There are both advantages and disadvantages of tracheotomy versus prolonged intubation and several factors must be considered in determining which is the most appropriate course for each child.
- There are a variety of techniques available to try to avoid tracheotomy in certain cases of upper airway obstruction.
- With few exceptions, tracheotomy in children should be performed in the operating room, under general anesthesia, with a secure airway.
- In infants and small children, a vertical incision in the trachea may be preferred. In older children and adolescents, either a vertical incision in the trachea or an inferiorly based flap can be employed.
- Stay sutures should be placed prior to making the incision to help retract the opening in the trachea intraoperatively and facilitate replacement of the tube in case of accidental decannulation in the early postoperative period.
- Pediatric tracheotomy can be performed with or without maturation of the stoma. Some surgeons feel that maturation of the stoma may decrease the morbidity of early accidental decannulation while leading to no increase in the rate of tracheocutaneous fistula formation.
- Children undergoing tracheotomy should be observed in the intensive care unit or in a special airway observation unit postoperatively for 5-to-7 days, until the first tracheostomy tube change, to help prevent morbidity from early postoperative complications, such as accidental decannulation and tracheostomy tube occlusion.
- Proper education and home care can help keep children with tracheostomy tubes safe and avert complications after discharge from the hospital.
- There are a variety of complications of pediatric tracheotomy that can be divided into intraoperative complications, early postoperative complications (less than 7 days), and late postoperative complications.
- There are several types of pediatric tracheostomy tubes available, in different widths, lengths, and materials; it is important to select the appropriate tracheostomy tube to meet each child's needs.
- The underlying reason for the tracheotomy influences the chance for successful decannulation; there must be adequate improvement in the problem that led to the tracheotomy prior to decannulation.
- Prior to decannulation, a complete airway endoscopy should be performed to evaluate for any tracheostomy-related problems and determine that there is no concerning areas of airway obstruction.
- Children who have a tracheostomy can have both impaired communication skills and abnormal swallowing function; it is important to involve speech pathologists in the care of children with tracheostomy tubes to help address both of these issues.

93 Ingestion Injuries and Foreign Bodies in the Aerodigestive Tract

Warren K. Yunker *Ellen M. Friedman*

Children less than 5 years of age routinely explore their environment by placing objects in their mouths. As such, they are at a significantly increased risk for both the accidental ingestion of harmful substances and foreign bodies becoming lodged within the aerodigestive tract. These events are potentially life threatening. As such, it is necessary for all Otolaryngologists to be familiar with the diagnosis and management of these conditions.

INGESTION INJURIES

Otolaryngologists have always been at the forefront of the diagnosis and management of caustic ingestion. In 1927, Dr. Chevalier Jackson was successful in lobbying for the special labeling of caustic materials. His campaign, which resulted in the prominent printing of "Poison" on various products, heralded the beginning of an overall increase in public awareness regarding the handling and storage of hazardous substances. Subsequent legislations, such as regulating maximum concentrations of hazardous agents and requiring child-resistant containers, not only further increased public awareness, but also significantly decreased the impact of hazardous chemical ingestion.

Over the last 100 years, the mortality from esophageal burns has decreased, while the management of their sequelae has improved. In the early 1900s, chronic esophageal strictures alone accounted for a mortality rate of more than 40%, with management of the unvisualized esophagus centering primarily on supportive care (1). With the evolution of diagnostic imaging and aerodigestive tract endoscopy, practitioners are able to more accurately diagnose and treat esophageal injuries.

Mechanism of Injury

The most common agents responsible for caustic ingestion fall into one of three categories: (a) alkalis, (b) acids, and (c) bleaches. Each of these three categories causes a distinct histologic reaction when it comes into contact with the mucosa of the upper aerodigestive tract.

Alkali agents cause liquefaction necrosis, wherein the mucosa disintegrates, allowing the agent to penetrate into the surrounding tissues. This is reflected in the finding of more oral and upper esophageal injury. Alkalis are usually odorless and tasteless, which, in the case of accidental ingestion, may allow for the consumption of large volumes. Ingestion of compounds with a pH between 9 and 11, such as many household detergents, rarely cause serious injury. However, ingestion of even small quantities of an alkali with a pH above 11 may cause severe burns. Specific examples of strong alkali are sodium hydroxides (lye, drain and oven cleaner, and dishwashing detergents) and sodium phosphates (dishwashing detergents and laundry detergents). Granular forms of detergents and cleaners are associated with a higher rate of injury than liquid forms because of their adherence to the mucosa. Another commonly ingested alkaline agent is hair relaxer (2–5). These agents denature structural proteins, thereby straightening curly hair. Fortunately, the degree of mucosal injury following hair-relaxer ingestion has been found to be mild with little to no adverse clinical effect. Unfortunately, alkaline agents may not be perceived by families to represent a potential hazard because of their ubiquitous nature and lack of childproof packaging.

Acidic agents result in coagulation necrosis, which causes a coagulum to form on the mucosa, thereby limiting deeper absorption until the agent reaches the stomach. In addition, these agents tend to have a low viscosity, which facilitates rapid transit to the stomach. Gastric injury following ingestion may result in gastric outlet obstruction or perforation, which is a potentially life-threatening complication as there can be multiorgan injury and rapid clinical decompensation (6). Fortunately, the bitter taste of acidic compounds may help to lower the volumes of accidental

ingestion. Examples of strong acids that may be found around the home are sulfuric acid (drain cleaner), hydrochloric acid (toilet bowl cleaner), sodium bisulfate (toilet bowl cleaner), and hydrofluoric acid (metal cleaner) (6).

Bleaches, which are essentially of neutral pH, are considered esophageal irritants. Large series of patients with bleach ingestion have shown no significant morbidity or mortality. For this reason, extensive workup of patients following bleach ingestion is not warranted (7).

The amount and type of agent ingested, the presence of food in the stomach, gastrointestinal transit time, and the presence of gastroesophageal reflux will all contribute to the extent and severity of injury following caustic ingestion. Initial contact of the caustic agent with the mucosa produces immediate changes that then progress over the following 2 to 3 days. After this acute phase, a latent period begins, during which stricture formation may occur. This process may proceed as rapidly as within 1 month, or slowly evolve over years. Superficial mucosal burns tend to heal without sequelae. Burns that are deep enough to disrupt the submucosa and muscular layer tend to be complicated by a significant loss of mucosa. In these cases, an intense inflammatory response develops in the burned area, with accompanying esophageal dysmotility. In response to the injury, fibroblasts produce a matrix of newly formed collagen fibers, which begin to contract 3 to 4 weeks after the initial insult. Contraction enables adhesive bands to form, which can then lead to the development of both pseudodiverticula and endoluminal strictures. Stricture formation may evolve to include both the submucosal and muscular layers. In general, only circumferential esophageal injuries lead to strictures severe enough to cause clinically significant morbidity.

Clinical Presentation

Caustic ingestions occur most frequently in children younger than 6 years, with the majority of cases occurring in children between 12 and 48 months of age (6). In general, the child has to be ambulatory and have access to cabinets or other areas where cleaning products are stored. The most common symptoms following a caustic ingestion are dysphagia, drooling, food avoidance, and vomiting. More ominous signs and symptoms, such as severe retrosternal or thoracoabdominal pain or tachycardia with hypotension, may be associated with significant gastrointestinal injury. Dysphonia or stridor may herald progressive airway obstruction. The prognostic significance of the presenting clinical signs and symptoms following caustic ingestion has been widely addressed in the literature (8,9). Although minor symptoms do not rule out the presence of relevant injury, an increased number of symptoms do correlate with a greater likelihood of significant injury. A recent Italian study of 102 children reported that the presence of three or more symptoms was an important predictor of severe esophageal burns (10). In the same series, the absence of signs and symptoms was associated with a very low relative risk of severe lesions. However, it is important to note that in this series, 2 of the 70 patients (2.8%) without symptoms had severe injuries on endoscopy.

Even the presence or absence of oral injuries, such as lip or buccal mucosa burns, does not accurately predict the presence or absence of more distal involvement. In a recent survey by Dogan et al. of 473 pediatric caustic ingestions, 240/389 (61%) patients without oral cavity burns had esophageal lesions found at endoscopy (11). A study by Hawkins et al. showed that 70% of patients with oropharyngeal burns did not manifest associated esophageal injuries (12). Therefore, neither the presence nor absence of visible injury on physical exam should influence further investigation.

Diagnosis and Treatment

The initial management of ingestion injuries focuses on the ABCs of resuscitation: airway, breathing, and circulation. Most childhood ingestions occur while the child is unsupervised. As a result, it may not be possible to obtain an accurate history, or information regarding the quantity and type of agent. Whenever possible, the parent or guardian should be asked to bring the container of the suspect agent to the physician's office or emergency room. In addition, in the United States there is 24-hour-a-day Poison Center hotline (1-800-222-1222) that should be contacted for help in identifying the pH of the ingested substance as well as for specific treatment recommendations. Any patient with stridor or drooling should undergo emergent laryngoscopy.

Patients with severe laryngopharyngeal injuries, including but not limited to edema, burns, or necrosis, should undergo emergent tracheotomy, rather than endotracheal intubation, in order to maintain and protect the airway. At the present time, it is unclear if either acids or alkalis present a greater risk, either short-term or long-term, to the airway and larynx following ingestion. Similarly, there is little to no published literature focusing on treatment algorithms for ingestion-related laryngeal injuries. As such, at present, we believe that the safest and most prudent course of action is to leave the tracheotomy in place until such time that the laryngopharyngeal injuries have fully evolved and stabilized. Only then the airway can be completely and thoroughly evaluated and decannulation contemplated. Due to a lack of evidence, we do not advocate the routine use of either prophylactic antibiotics or systemic steroids in these cases.

Once the airway is secure, direct endoscopic visualization of the esophagus is the most reliable and accurate method of determining the extent of esophageal injury. However, the timing of endoscopy is crucial. If the examination is performed earlier than 12 hours following ingestion, adequate time may not have passed for the injury to fully manifest, and as a result the examination may underestimate

the extent of injury. Yet, examination during the period of structural weakness of the esophageal wall will increase the risk of iatrogenic injury during the examination. Therefore, endoscopy should be performed between 12 and 48 hours following ingestion to achieve the highest degree of patient safety while yielding the most information (8).

Esophageal injury is graded at the time of endoscopy to direct therapy, as the degree of injury is correlated with the likelihood of complications, morbidity, and mortality. Several esophageal injury-grading systems have been proposed in the literature (13–16). Unfortunately, there is no one system that has been widely adopted. Regardless of the grading system used, the goal is to risk-stratify patients and direct subsequent therapy. The classification system proposed by Estrera et al. segregates injuries into four grades (Table 93.1) (16). Grade 1 injuries consist of mucosal edema and erythema. Grade 2 injuries consist of mucosal erythema, sloughing, superficial ulceration, and noncircumferential exudates. Grade 3 injuries are associated with deep mucosal ulceration or circumferential sloughing. Grade 4 injuries are characterized by eschar, full thickness changes, or perforation. Another commonly employed esophageal injury grading system is the one proposed by Zargar et al. (14). However, for purposes of brevity and clarity it will not be reviewed here.

Traditionally, in these patients esophagoscopy was performed using a rigid, open tube endoscope, and the teaching was that the endoscope should not be advanced beyond areas of transmural or circumferential injury due to the heightened risk of iatrogenic perforation. In recent years, a considerable number of patients with ingestion injuries are now being initially assessed with flexible endoscopes. There is little to no published literature comparing the risk of rigid and flexible esophagoscopy in inducing esophageal perforations following caustic ingestion. As such, at present, we believe that the safest and most prudent course of action is still to avoid advancing the esophagoscope, be it flexible or rigid, beyond areas of transmural or circumferential injury.

If patient assessment occurs more than 72 hours postingestion, esophagoscopy should be avoided. In this situation, radiographic contrast studies should be used for initial assessment.

TABLE 93.1 ESOPHAGEAL INJURY GRADING SYSTEM

Grade	Description
1	Mucosal edema and erythema
2	Mucosal edema, sloughing, ulceration, and noncircumferential exudates
3	Deep mucosal ulceration or circumferential sloughing
4	Eschar, full thickness changes, and perforation

Patients with grade 1 injury on endoscopy can usually be managed with 24 to 48 hours of nothing by mouth (NPO) with IV hydration and subsequently restarted on a regular diet and discharged from hospital. Patients grade 2 and 3 injuries should be kept NPO with nutrition supplied either enterally (via a nasogastric [NG] tube that was inserted under direct vision in the operating room or using fluoroscopy) or parenterally. NPO status is usually maintained for 7 to 10 days, followed by a contrast swallow study prior to commencing PO feeds. In the event of a perforation, emergency surgery may be required. In rare instances, an emergency esophagectomy or gastrectomy may be needed.

The use of neutralizing agents is not recommended because they have not been shown to be efficacious and may lead to increased thermal injury. Gastric lavage and induced vomiting with emetics, such as ipecac, are also contraindicated as vomiting will cause repeated exposure of the agent to the esophageal mucosa and potentially increase the degree of injury. Similarly, blind passage of an NG tube should be avoided due to the potential for iatrogenic esophageal perforation.

Starting in the 1960s, patients with esophageal ingestion injuries were frequently treated with systemic steroids in an attempt to decrease or prevent stricture formation. However, patients with isolated grade 1 burns rarely, if ever, develop strictures (14). In comparison, most patients with grade 3 burns develop strictures regardless of therapy (17). Patients with severe burns are at high risk for other complications, such as infection and perforation, and the use of steroids may, in fact, make the esophageal tissue more prone to perforation. In addition, a recent systemic review on the use of steroids in second-degree caustic esophageal injuries did not support the use of steroids in these patients (18). As such, it is our recommendation that systemic steroid therapy no longer be routinely employed in the management of caustic esophageal injuries.

Similarly, the use of prophylactic antibiotics does not appear of benefit in managing caustic esophageal burns (19). It is our recommendation to withhold antibiotics unless the patient develops signs or symptoms of a secondary infection.

Postinjury gastroesophageal reflux may act synergistically to further damage the esophagus, thereby promoting granulation tissue and possibly increasing scar formation. As such, the routine use of antireflux therapy has been recommended to help prevent secondary reflux-associated esophageal injury (20–22).

Complications

Complications arising from caustic ingestion may arise either acutely following ingestion or arise over a period of months to years. Acute complications include, but are not limited to, esophageal perforation, tracheoesophageal fistulae, gastric perforation, mediastinitis, peritonitis, pneumonia, sepsis, and death. If the patient develops sepsis,

or other signs of esophageal perforation or mediastinitis, urgent exploration and drainage is indicated.

The most common long-term complication of caustic ingestion is stricture formation. Strictures may be mild, requiring only slight alterations of diet, or may be severely debilitating. In addition, they may form in multiple locations and can vary in length or severity (Fig. 93.1). Since the 1920s, esophageal dilatation has been used to improve the esophageal lumen. Balloon catheter dilation can be used safely and effectively in children in whom esophageal strictures develop after caustic injury, although it may be associated with higher complication and failure rates when compared to its use in children with congenital esophageal strictures (23). Long-term management of esophageal strictures secondary to caustic ingestion involves repeated serial dilations. Recently, the topical application of the fibroblast inhibitor mitomycin C has emerged as a successful adjunctive therapy in the management of esophageal strictures (24,25). Although the data regarding the use of mitomycin C is promising, the optimal frequency of application and long-term outcomes are, as of yet, unclear.

Other long-term sequelae of caustic ingestion include the development of a hiatal hernia, reflux esophagitis, peptic stricture, and esophageal cancer. The association with esophageal carcinoma is unusual in that an equal male-to-female ratio of occurrence exists and it presents in a younger age group than is usually affected. In a large series of esophageal carcinomas, a 1% to 4% incidence of caustic ingestion was found in the clinical histories (23). Although the exact degree of increased risk for carcinoma is unknown, it has been estimated to be 1,000-fold. Fortunately, because these carcinomas tend to arise within the scar tissue, their tendency for distant metastasis is lower, and potential cure with resection is higher. For this reason alone, long-term follow-up of patients with esophageal stricture is warranted, regardless of their symptoms. Any patient who develops dysphagia years after a caustic injury should undergo radiographic evaluation and endoscopy.

Figure 93.1 Barium swallow demonstrating esophageal stricture formation following caustic ingestion. This stricture developed within 1 month of lye ingestion.

AERODIGESTIVE FOREIGN BODIES

Life-threatening foreign-body incidents occur in two forms: (a) foreign-body aspiration, wherein the object is lodged within the laryngotracheobronchial axis; and (b) foreign-body ingestion, in which the object is lodged within the esophagus. Both forms can present with the acute onset of airway symptoms, and share significant associated morbidity and mortality.

Foreign-Body Aspiration

In the United States, over the last quarter century the incidence of foreign-body aspiration has remained relatively consistent, and this is unlikely to change as long as children continue to place objects in their mouth as a means of exploring their surroundings. Fortunately, there has been a dramatic decrease in childhood deaths from asphyxiation by ingested objects; although the associated morbidity in survivors or prolonged hypoxia remains considerable (26).

The most common age group affected is toddlers between 2 and 4 years of age. Case series from the last decade reflect that children younger than 5 years account for approximately 84% of cases, while children younger than 3 years account for 73% (27). The high incidence in this age group reflects the oral tendency of these children. In addition, children of this age often do not have full posterior dentition or mature neuromuscular mechanisms for appropriate swallowing and airway protection. Boys are affected more frequently than girls in a ratio of approximately 2:1. The acute episode is heralded by gagging and choking; however, because the toddlers may be out of the parents view during the acute episode, this period of acute distress may go unwitnessed, making it more difficult to be sure of the diagnosis. If the foreign body descends further down the tracheobronchial axis, active distress may subside. Overall, symptoms vary in severity depending on the size and composition of the foreign body, as well as its location, degree of airway obstructing, and the surrounding tissue reactions.

Since up to 50% of aspirations may go unwitnessed, the differential diagnosis for a patient with nonspecific pulmonary complaints, such as intermittent coughing or wheezing, must include airway foreign body. Without a high degree of suspicion for foreign-body aspiration, physicians may proceed with allergy testing, asthma therapy, or treatment of a presumed pulmonary infection, while

overlooking the possibility of foreign body. It is not uncommon for a patient to be treated for several months, including repeated hospitalizations, before proceeding to bronchoscopy for diagnosis and removal of the retained foreign body. Therefore, any patient with a prolonged nonspecific pulmonary complaint, even in the absence of an aspiration history, should raise the question of a retained foreign body. It is not surprising that in a review by Cohen et al. of 143 cases of foreign-body aspirations in children demonstrated that only 41% were seen by a physician 1 day following the aspiration event (28). Likewise, Reilly et al. noted that 15% of pediatric aerodigestive foreign-body injuries were incorrectly diagnosed at the time of initial physician assessment and that foreign-body aspirations were seven times more likely to have a delay in diagnosis than were foreign-bodies lodged in the esophagus (29).

The most commonly aspirated objects in the pediatric population are food products. Most are peanuts, but raisins, seeds, and other nuts are also commonly encountered. Beans and seeds absorb water over time and with subsequent swelling can rapidly result in a complete bronchial obstruction. Other organic foreign bodies can also illicit an inflammatory reaction in the surrounding tissue, and may result in arachnoid bronchitis. This is seen as a spidery pattern on chest radiograph, even if the foreign body itself is radiolucent. Inert foreign bodies are less inflammatory and may remain in one position for extended periods of time without causing increasing degrees of obstruction. The most common inert bronchial foreign bodies are pieces of toys. In the past, plastic toy pieces were often radiolucent and therefore undetectable on chest radiograph. Several companies, including 3M and Mattel, have sponsored research into, and the development of, radiopaque plastic. Unfortunately, however, this material is not routinely employed by all toy manufacturers. Another common childhood toy associated with aspiration is the latex balloon. The aspiration of latex balloon has a high morbidity and has prompted the move toward Mylar balloons for children.

McGuirt et al. found that the elderly also have a significant incidence of foreign-body aspiration, which is perhaps due to their lack of dentition (30). The foreign bodies most commonly aspirated by adults include food products and portions of dental prosthesis.

Workup

Chest auscultation most commonly will reveal decreased breath sounds on the obstructed side, in addition to wheezing and decreased localized air entry. The chest findings may be misinterpreted as asthma or pneumonia. As such, in the setting of prolonged, or unusual symptoms that are not responsive to routine management a bronchoscopy is indicated.

The most important noninvasive study to evaluate for foreign bodies is the chest radiograph (Fig. 93.2). However, Strome showed that up to 25% of plain chest radiographs of patients with known foreign bodies are within normal limits (31). This may be due to the fact that the hallmark radiographic signs, associated with foreign-body aspiration, mediastinal shift, and air trapping, are most readily demonstrated only on expiratory plain film or fluoroscopy, instead of a single inspiratory view (Fig. 93.2). In children unable to comply with inspiratory and expiratory radiographs, right and left lateral decubitus films may be helpful. In the unobstructed setting, the dependent lung will deflate on lateral decubitus positioning. If the dependent lung remains fully aerated, obstruction exists, suggesting the presence of an obstructing foreign body (Fig. 93.3).

Note how the left lung does not change in volume despite changes in patient position. *Image courtesy of Dr. J. Crowe.*

However, even with the use of fluoroscopy, approximately 10% of patients with an aspirated foreign body will be missed. Therefore, even in the presence of a normal radiographic exam, a patient with a suspicious history and clinical course should be considered for endoscopic evaluation.

Making the accurate diagnosis of an airway foreign body is complicated due to the frequent combination of an unwitnessed aspiration episode, clinical picture consistent with several other common entities, and a lack of foolproof confirmatory diagnostic tests. For this reason two different outcomes may arise; in one group the diagnosis of an aspirated foreign body may be delayed and another group of patients may undergo negative bronchoscopy in search of a foreign body when the patient actually has pneumonia, asthma exacerbation, or bronchitis. CT scans and virtual bronchoscopy can significantly help in accurately diagnosing airway foreign bodies. Specifically, chest CT scans are able to reliably identify nonradioopaquic foreign bodies and can deliver a relatively low dose of radiation exposure. Hong et al. (32) showed that chest CT was highly sensitive in identifying a foreign body as well as surrounding secondary parenchymal changes and mediastinal diseases. Earlier consideration of the use of chest CT scans in the evaluation of these children could decrease the delay in reaching the correct diagnosis in positive children and could also decrease the number of negative bronchoscopies performed in children with other processes.

Treatment

An experienced team that includes an anesthesiologist experienced in spontaneous ventilation anesthesia, an endoscopist, and a nurse or surgical technician should perform bronchoscopy. To help ensure that a patient with a precarious airway does not deteriorate into a critical situation, excellent communication among all team members is absolutely essential. The endoscopist must remember to exclude the possibility of multiple foreign bodies, which can occur in up to 5% of cases (30). After the removal of a foreign body, the endoscope is reintroduced into the trachea to search for additional foreign bodies and to assess any trauma to the tracheal mucosa.

The actual removal of the foreign body presents its own set of challenges. Edema, granulation tissue, and bleeding frequently impede the visualization and extraction of the foreign body. In addition, postinstrumentation airway edema, which may further impair the patient's airway, is not uncommon. Fortunately, this usually responds to intravenous dexamethasone and nebulized epinephrine. Attempts to manipulate the location of the foreign body through patient positioning should be avoided, as it is rarely successful and may dislodge the object and allow it to progress to an even more distal location in the tracheobronchial tree.

Foreign-Body Ingestion

It is estimated that approximately 1,500 people die annually from complications related to foreign-body ingestion, with children being the most common victims (33). Presenting symptoms depend upon the size of the foreign body, its location, and duration of impaction. In children, esophageal foreign bodies frequently present with a mild to moderate degree of respiratory distress (33,34). This is a result of the extreme compliance of the party wall between the

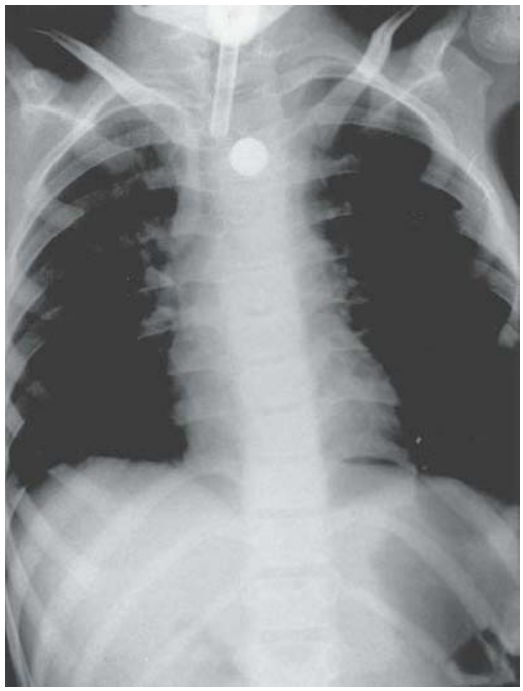

Figure 93.4 Chest radiograph of a child with a coin lodged in the esophagus. In this case, an emergency tracheotomy had been performed to relieve the severe airway distress the unsuspected foreign body was causing.

esophagus and trachea. The mass effect of an impact object in the esophagus, therefore, can have significant impact on the airway. Figure 93.4 is a radiograph of a patient who presented to the emergency department in severe respiratory distress and underwent emergency tracheotomy. On the postoperative chest radiograph, the source of the airway obstruction was found to be an esophageal foreign body. It is important to recognize that dysphagia and drooling may actually present as late, rather than as the initial symptoms of an esophageal foreign body.

In the Unites States and Europe, coins are the most commonly ingested pediatric foreign body. Other commonly ingested items include toys, toy parts, sharp objects, disc batteries, fish bones, and food. The most commonly ingested foreign body resulting in fatality is a segment of hotdog. Coins that lodge in the esophagus typically settle in one of three locations. Approximately 60% to 70% become lodged at the upper esophageal sphincter or cricopharyngeus muscle, 10% to 20% impact in the mid-esophagus at the level of the aortic notch, and 20% are held up by the lower esophageal sphincter (Fig. 93.5) (34). If a foreign body becomes lodged elsewhere in the esophagus, the possibility of an underlying abnormality, such as a congenital esophageal stricture, should be considered.

Whenever possible, evaluation of patients with a suspected esophageal foreign body should include both anteroposterior and lateral x-rays to verify that the object is indeed in the esophagus rather than in the airway (Fig. 93.5). Endoscopy under general anesthesia with a protected airway is the mainstay of esophageal foreign body management. However, esophagoscopy is not without risks, including pharyngeal bleeding, accidental extubation, hypoxia, esophageal perforation, and mediastinitis. Emergent removal of the foreign body should be performed in symptomatic patients unable to swallow their own secretions or who are experiencing acute respiratory symptoms. However, in these situations

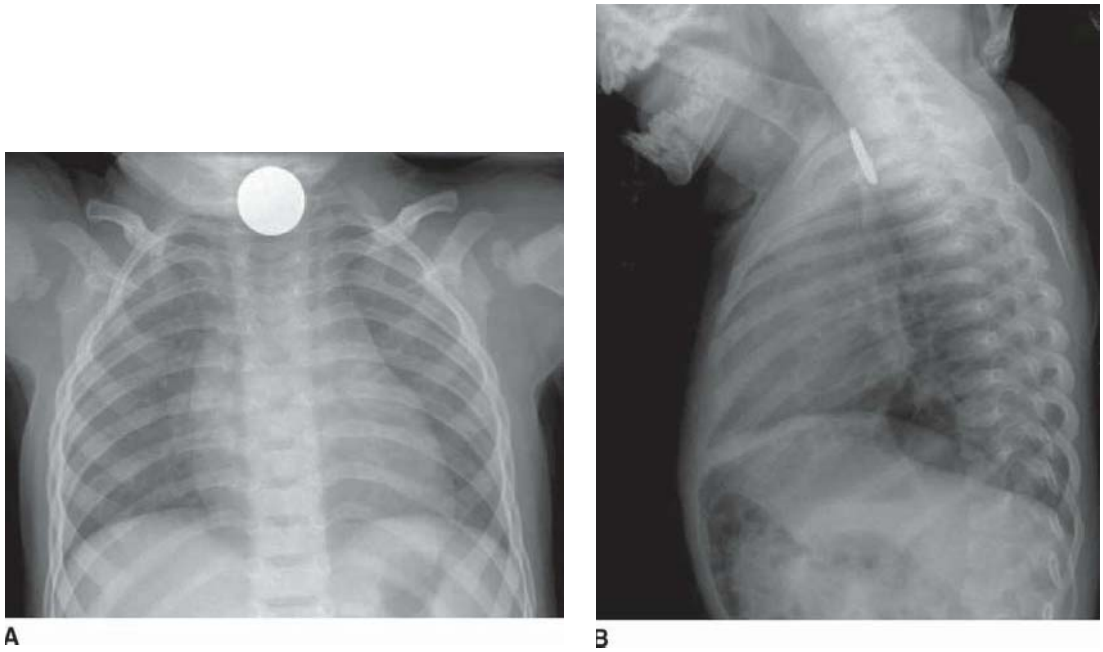

Figure 93.5 Radiographs of two different children with foreign bodies lodged at the level of the upper esophageal sphincter (UES). Anteroposterior (AP) **(A)** and lateral **(B)** view of coin lodged at the UES. AP *(Continued)*

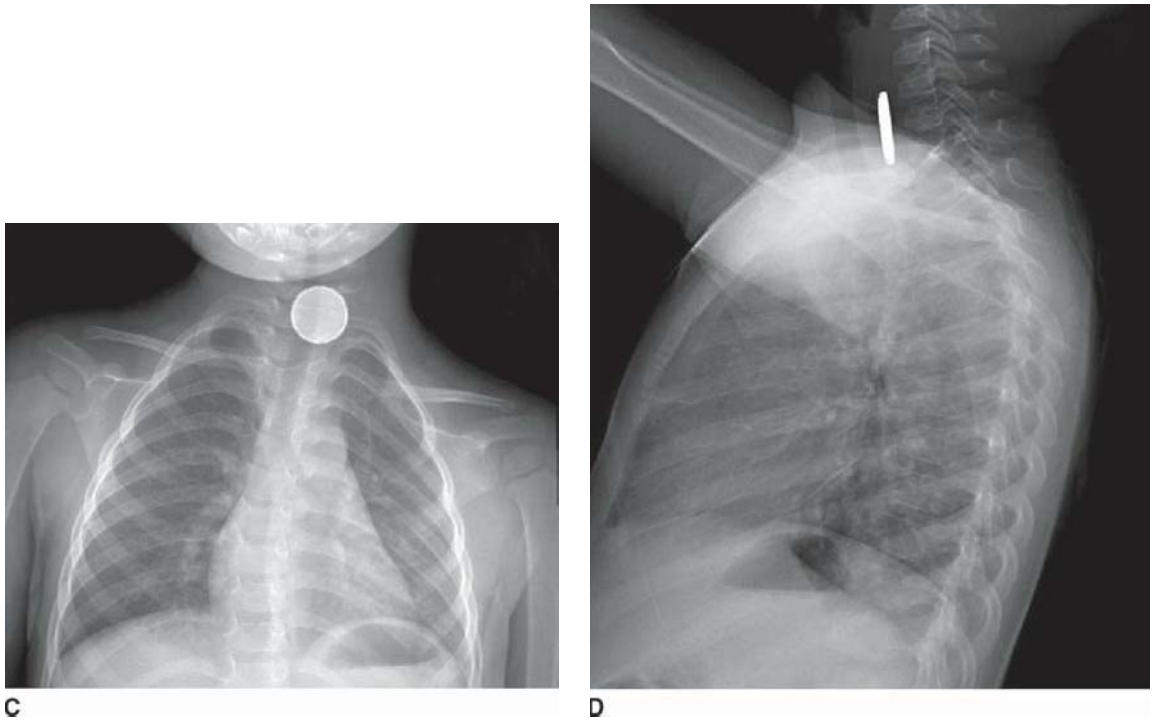

Figure 93.5 *(Continued)* **(C)** and lateral **(D)** views of a disc battery lodged at the UES. Note the "double-ring" that is characteristic of a disc battery in **C**. the risk of aspiration of gastric contents is higher and appropriate precautions should be taken. In patients who are asymptomatic, endoscopy can be postponed for 12 to 24 hours. There are two important exceptions to this principle. The first is if the foreign object appears to be a disc battery. The second is if the foreign object is sharp and/or has the potential to perforate the esophagus, such as an open safety pin. In these situations, emergency endoscopy is required. If there is a significant delay between the time of diagnosis and endoscopy, a repeat radiograph should be obtained immediately prior to the procedure to verify that the object has not passed into the stomach. Following extraction of the foreign body, the esophagoscope should be reinserted to rule out the potential of a second foreign body, as well as to evaluate and document any mucosal injury (35). In instances where the object has passed into the stomach, the patient can usually be managed expectantly.

Although it is technically possible to remove an esophageal foreign body under fluoroscopy in the radiology suite with the use of a balloon catheter, it is potentially dangerous. Although dislodging a foreign body from the esophagus into the larynx, resulting in airway obstruction, is uncommon, it does not seem to be a justifiable risk in the presence of a safer alternative.

Disc Battery Ingestion

The disc battery is the most potentially harmful of the esophageal foreign bodies, and as such deserves special comment. These batteries are becoming increasingly common in children's toys, and, not surprisingly, so is their ingestion. In 1998, the American Association of Poison Control Centers reported a total of 2,063 disc battery ingestion, while in 2007, 10,213 cases of battery exposures were documented across the United States in 2007 (36).

A classic feature of disc battery ingestion is the "double-ring" seen on chest x-ray (Fig. 93.5). However, the absence of this finding does not exclude the possibility of a disc battery and the clinician must maintain a high index of suspicion. The damage caused by these batteries is a combination of leaking alkaline contents, low-voltage electrical discharge and pressure necrosis, and substantial injury to the esophageal mucosa may occur as early as 1 hour after ingestion (37,38). Given the rapidity of onset and potential for extensive injury, a disc battery lodged in the esophagus mandates emergency esophagoscopy. When substantial esophageal erosion is detected, bronchoscopy to evaluate the tracheal wall for a fistula, as well as a postoperative chest x-ray and esophagogram are recommended to evaluate for esophageal perforation (39,40). Management of foreign body-induced esophageal injuries, be it disc battery or other foreign body, is similar to that of caustic ingestion.

In contrast, batteries that have traversed the esophagus and are situated in the stomach require a less urgent approach as they are likely to uneventfully pass through the remainder of the gastrointestinal tract, typically within 48 hours (34).

OTHER CONSIDERATIONS

An interesting finding concerning caustic ingestions and foreign-body aspirations is the possibility of child abuse (41–43). Negligence, or an act of omission, may result in an accident, but it may also be the sign of a troubled family and a child at risk. Intentional abuse, or an act of commission, is much more worrisome. There have been an increasing number of cases demonstrating child abuse or Munchausen syndrome by proxy with foreign-body or caustic ingestions. Some cases are obvious, others are more difficult to recognize. Increased vigilance will aid and protect children at risk. Most states mandate the reporting of suspicious episodes.

HIGHLIGHTS

- Caustic ingestion can be classified as alkaline, acidic, or neutral.
- Alkaline substances cause liquefaction necrosis, whereas acidic substances cause coagulation necrosis. Neutral agents, such as bleach, are mild esophageal irritants.
- The initial management of a caustic ingestion focuses on the ABCs of resuscitation: airway, breathing, and circulation. Poison control should be contacted at time of presentation.
- Esophagoscopy should be performed 12 to 48 hours following caustic ingestion for both diagnostic and prognostic purposes.
- Current literature does not support the use of either prophylactic antibiotics or systemic steroids in the management of caustic esophageal injuries.
- An esophageal foreign body may present with respiratory distress rather than dysphagia or drooling.
- An airway foreign body should be suspected in any patient who presents with prolonged or unusual pulmonary symptoms.

Recurrent Respiratory Papillomatosis

94

Craig S. Derkay *Cristina M. Baldassari*

In discussing recurrent respiratory papillomatosis (RRP) of the aerodigestive tract, it is helpful to review our current knowledge regarding the etiology of the disease, including some basic information on human papillomavirus (HPV), the histopathology of respiratory papillomas, as well as the epidemiology of the disease and risk factors for its transmission. This chapter also addresses the common clinical features seen in children with RRP, including the pertinent findings on history, physical examination, endoscopy, and imaging studies. Surgical treatments, including the use of laser and nonlaser technologies, also are addressed. Additionally, potential nonsurgical adjuvant therapies and their current indications for use are discussed. Complications of the disease itself as well as of its treatment are covered. A staging system for following patients with RRP is presented along with other new horizons for research and treatment of this frustrating entity.

RRP is a disease of viral etiology, caused by HPV types 6 and 11, associated with exophytic lesions of the airway. Although it is a benign disease, RRP has potentially morbid consequences due to its involvement of the airway, propensity to recur, and to the risk of malignant conversion.

RRP is both the most common benign neoplasm of the larynx among children and the second most frequent cause of childhood hoarseness (1). The disease is often difficult to treat because of its tendency to recur and spread throughout the respiratory tract. Although it most often involves the larynx, RRP may involve sites anywhere in the entire aerodigestive tract. The course of the disease is variable, with some patients experiencing spontaneous remission and others suffering from aggressive papillomatous growth, requiring multiple surgical procedures over many years.

In most pediatric series, RRP is diagnosed between 2 and 4 years of age with a delay in diagnosis from the time of onset of symptoms averaging about 1 year (2,3). Seventy-five percent of the children have been diagnosed before their fifth birthday (4). It is estimated that 1,500 to 2,500 new cases of childhood-onset RRP occur in the United States each year. The incidence among children in the United States is estimated at 4.3 per 100,000 children, translating into more than 15,000 surgical procedures at a total cost of more than $100 million per year (5). Anecdotal observations suggest that most patients are first born; have young, primigravid mothers; and come from families of low socioeconomic status (5–7). The clinical course is unpredictable, with malignant transformation possible in patients with long-standing aggressive disease.

RRP may have its clinical onset during either childhood (juvenile onset recurrent respiratory papillomatosis, JORRP) or adulthood (adult onset recurrent respiratory papillomatosis, AORRP). Of these two distinct forms, JORRP is generally more aggressive. The aggressive form of RRP, although most prevalent in children, can also occur in adults. Children whose RRP was diagnosed at younger ages (less than 3 years) have been found to be 3.6 times more likely to have more than four surgeries per year and almost 2 times more likely to have two or more anatomic sites affected than were children whose RRP was diagnosed at later ages (greater than 3 years) (8,9).

ETIOLOGY

Human Papillomavirus

HPV is a small DNA-containing, nonenveloped icosahedral (20-sided) capsid virus with a double-stranded circular deoxyribonucleic acid 7,900 base pairs long. Until the 1990s, HPV had been suspected but not confirmed as the causative agent in RRP. This uncertainty developed from an inability to culture the virus *in vitro*, and from the failure to demonstrate viral particles consistently in papilloma lesions using electron microscopy or HPV antibodies. Today, with the use of viral probes, HPV DNA has been identified in virtually every papilloma lesion studied. The

most common types identified in the airway are HPV 6 and HPV 11, the same types responsible for genital warts. Specific viral subtypes may be correlated with disease severity and clinical course. Children infected with HPV 11 appear to have a more obstructive airway course early in the disease and a greater need for tracheotomy (9,10).

HPVs are grouped on the basis of genetic homology, with viruses that exhibit less than 90% identity in specific regions of the viral genome being defined numerically as separate types. On this basis, nearly 100 different HPV types have been identified. These groupings correlate with tissue preference as well as similarities in pathophysiology. Groups associated with mucosal lesions in the aerodigestive and genital tracts include HPV types 6 and 11 with a low malignant potential; HPV 16 and 18 with a much higher malignant potential; and HPV 31 and 33 with a malignant potential that lies somewhere in between. At least 90 different types of HPV have been identified and are designated by numbers (i.e., HPV 6). The closer the numbers, the more similar the viral subtypes are in their clinical manifestations.

The induction of cellular proliferation is a fundamental property of HPV though its mechanism of action remains unclear. The present understanding is that HPV establishes itself in the basal layer, where viral DNA enters the cell and is transcribed into RNA which is then translated into viral proteins. The genome consists of three regions: an upstream regulatory region and the two regions named according to the phase of infection in which they are expressed, the early (E) and late (L) regions. The E region genes are involved in potent oncogenes that are responsible for the replication of the viral genome, interaction with host cell intermediate filaments, and transforming activities. The L region genes encode the viral structural proteins (11). Several factors are involved in the regulation of cell proliferation.

It is likely that the host immune system plays an important role in the pathogenesis of HPV-induced lesions. Both humoral and cellular immune responses may be compromised in children with RRP and a patient's immunocompetence may also influence the clinical course of disease. The role of cytokines such as interleukin-2, interleukin-4, and interleukin-10 and expression of the major histocompatibility complex antigens in the malfunction of the cell-mediated immune response in children with RRP have been demonstrated (12). Papillomas with a reduced expression of these antigens may evade immune surveillance and allow the disease to progress more rapidly.

HPV is thought to infect stem cells within the basal layer of epithelium (13–15). Following infection of the stem cells, the viral DNA can either be actively expressed, or it can exist as a latent infection in epithelium that remains clinically and histologically normal. During latency, there is very little viral RNA present. In fact, HPV DNA can be detected in normal-appearing mucosa in RRP patients who have been in remission for years, explaining why reactivation and clinical recurrence can occur following many years of remission (16–18). Thus, reactivation of viral expression can occur any time following establishment of a latent infection. Adult-onset respiratory papillomas could reflect either activation of virus present since birth or an infection acquired in adolescence or adult life. Gene products of early genes E6 and E7, and possibly E5, are required for papilloma induction, but the details of the mechanism of HPV activation are unknown. In order to "cure" RRP, it is necessary to modulate the host response to the virus and, ideally, eliminate the latent infection.

The universality of HPV in the lower genital tract rivals that of any other sexually transmitted disease in humans. It is estimated that at least 1 million cases of genital papillomas occur per year in the United States, affecting about 1% of the population (19). These most often manifest as condylomata acuminata involving the cervix, vulva, or other anogenital sites in women or the penis of male sexual partners of affected women. In addition, it is estimated that colposcopic (subclinical) changes affect nearly 5 million US women. An additional 14 million women, or about 10% of the female population of child-bearing age, are DNA positive but have no visible lesions while more than 80 million women, or 60% of the at-risk population, are HPV antibody positive but DNA negative. The incidence of HPV infections in sexually active young college women is high, with a cumulative incidence of 43% over a 36-month period in a recent study (20). Clinically apparent HPV infection has been noted in 1.5% to 5% of pregnant women in the United States (21). As in RRP, HPV 6 and 11 are the most common subtypes identified in cervical condylomata.

Recurrent Respiratory Papillomatosis

Histologically, RRP appears as pedunculated masses with fingerlike projections of nonkeratinized stratified squamous epithelium supported by a core of highly vascularized connective tissue stroma (Fig. 94.1). The basal layer may be either normal or hyperplastic, and mitotic figures are generally limited to this layer. Cellular differentiation appears to be abnormal, with altered expression and production of keratins. The degree of atypia may be a sign of premalignant tendency.

RRP lesions occur most often at anatomic sites in which ciliated and squamous epithelium are juxtaposed (22). The most common sites for RRP are the limen vestibuli, the nasopharyngeal surface of the soft palate, the midline of the laryngeal surface of the epiglottis, the upper and lower margins of the ventricle, the undersurface of the vocal folds, the carina, and at bronchial spurs (6). In tracheotomized patients, RRP is often encountered at the stoma and in the mid-thoracic trachea, areas that might be considered iatrogenic squamociliary junctions.

Papilloma lesions may be sessile or pedunculated and often occur in irregular exophytic clusters (Fig. 94.2). Typically, the lesions are pinkish to white in coloration. Iatrogenic implantation of papilloma may be preventable

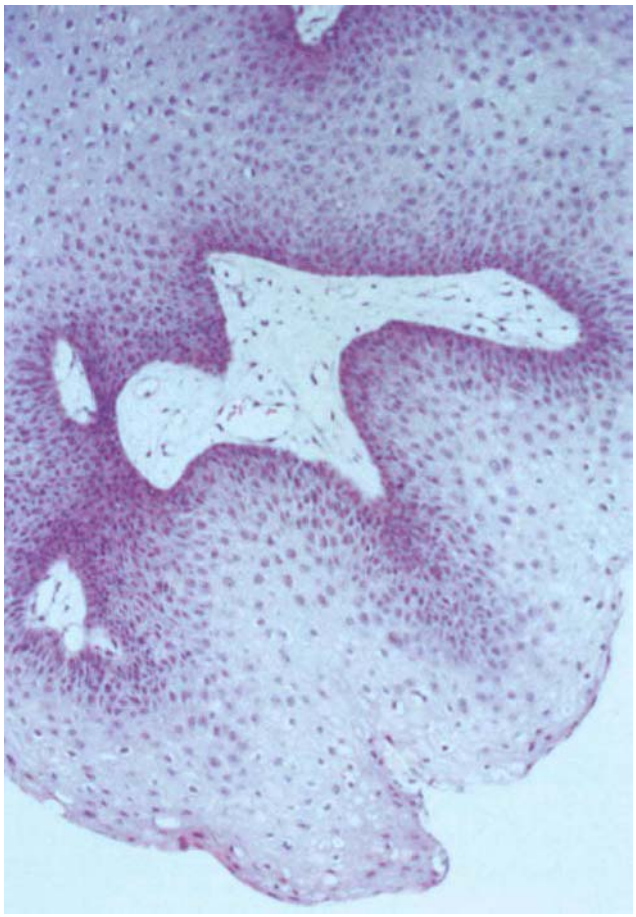

Figure 94.1 Histologic section of papilloma, demonstrating fingerlike projection of nonkeratinized stratified squamous epithelium and vascularized connective tissue stroma.

by avoiding injury to nondiseased squamous or ciliated epithelium adjacent to areas of frank papilloma. Ciliated epithelium undergoes squamous metaplasia when exposed to repeated trauma and is replaced with nonciliated epithelium that creates an iatrogenic squamociliary junction.

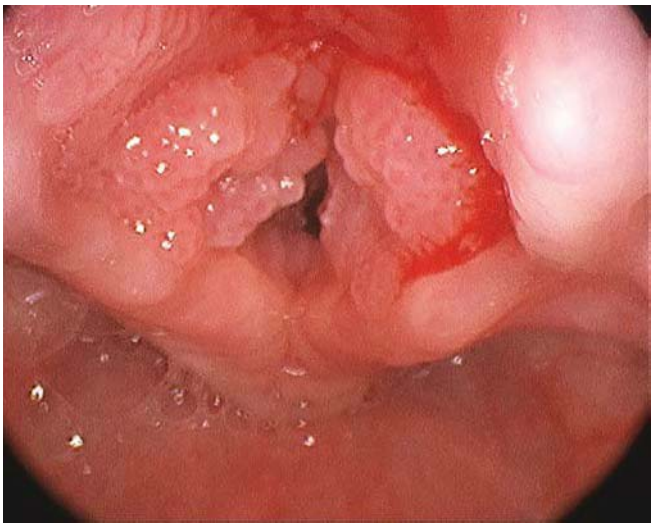

Figure 94.2 Papilloma lesions involving the laryngeal inlet.

This may also explain the observation that RRP flourishes in the presence of uncontrolled gastroesophageal reflux with an increased incidence of laryngeal scarring (23).

EPIDEMIOLOGY

RRP may affect people of any age, with the youngest patient identified at 1 day of age and the oldest at 84 years (5). JORRP (arbitrarily defined as patients diagnosed at less than 12 years of age) is most often diagnosed between 2 and 4 years of age. The distribution of RRP among boys and girls is approximately equal, and there are no apparent differences in surgical frequencies by gender or ethnicity (8). AORRP peaks between the ages of 20 and 40 years and has a slight male predilection. The mode of transmission for AORRP is unknown. While it is postulated that transmission is from either latent virus present from birth or adult exposure through sexual contact, these theories have yet to be fully substantiated.

Numerous studies have been performed to elucidate the true incidence of RRP. The national registry of children with RRP, composed of the clinical practices at 22 pediatric otolaryngology sites (arguably a skewed population of more severely affected children), calculates a mean number of procedures at 19.7 per child, with an average of 4.4 procedures per year (8). Children diagnosed before 3 years of age were found to be 3.6 times more likely to require more than four surgical procedures per year and 2.1 times more likely to have two or more anatomic sites involved than those diagnosed after their fourth birthday (8). Children with disease progression are diagnosed at younger ages than those who remain stable or become disease-free (24). Younger children are more likely to have persistent disease and more often experience an increased number of surgeries in the first year following diagnosis (25).

In a survey of practicing otolaryngologists in the United States, half of the adults with RRP had required fewer than five procedures over their lifetime compared with less than 25% of the children. Approximately equal percentages of children and adults (17% children vs. 19% adults) had very aggressive RRP (defined as requiring more than 40 lifetime operations), although adults had more years to accumulate these operations (5). The true incidence and prevalence of RRP are uncertain. In a Danish subpopulation incorporating 50% of the population of that country, the incidence of laryngeal papillomatosis was 3.84 cases per 100,000 (26). The rate among children was 3.62 per 100,000, whereas adult-onset cases occurred at a rate of 3.94 per 100,000. These figures are comparable with those found in a US survey, which estimated an incidence in the pediatric population of 4.3 cases of RRP per 100,000 children and 1.8 cases of RRP per 100,000 adults (5). Armstrong et al. (27) estimated that there are 80 to 1,500 incident cases of JORRP annually in the United States and 700 to 3,000 prevalent cases of JORRP based upon a 1999 epidemiologic analysis of two US cities.

Recently, Campisi et al. created a national database incorporating all children (less than 14 years old) with RRP in Canada treated by Pediatric Otolaryngologists. This study found the national incidence of JORRP from 1994 to 2007 to be 0.24 per 100,000 with a prevalence of 1.11 per 100,000 (28). These estimates are significantly lower than several previous studies, but similar to a population-based study of RRP patients in Seattle and Atlanta (27). The authors attribute this discrepancy to either over-estimation by other studies based on extrapolated data or higher incidences in other countries.

Interestingly, a recent pilot study of a large database of publicly and privately insured patients in the United States consistently showed that RRP incidence was higher in publicly insured patients compared to those with private insurance (3.21 vs. 1.98 per 100,000, respectively) (29). An explanation for this finding is that patients with public insurance often come from a lower socioeconomic level than those with private insurance. A cross-sectional study of all active JORRP patients from the Hospital for Sick Children in Toronto showed that nearly half of these patients were below the poverty line in Canada (30). This study, however, showed no correlation between socioeconomic status and severity of disease.

RRP places a large economic burden on individual patients and their families as well as our society as a whole. On average, a child presenting to an academic center in the United States with RRP requires 19.7 procedures over their lifetime, with a mean frequency of procedures being 4.4 per year (5). Approximately equal numbers of adults and children with RRP (17% vs. 19%, respectively) will have aggressive disease requiring more than 40 lifetime procedures. The average lifetime cost to treat one patient with RRP has been estimated at $60,000 to $470,000 in the United States (29).

In addition to the economic burden, RRP significantly impacts quality of life. Lindman et al. (31) utilized a validated quality of life instrument to assess patients with JORRP. Compared with healthy controls, children with RRP self-reported significantly poorer quality of life in the areas of psychosocial health, social functioning, and school functioning. Children with RRP had quality of scores similar to children with other chronic medical conditions.

Transmission

The precise mode of HPV transmission remains unclear. Several studies have convincingly linked childhood-onset RRP to mothers with genital HPV infections, whereas circumstantial evidence suggests that adult disease may be associated with oral–genital contact. Retrospective and recent prospective studies have confirmed that HPV may be passed by vertical transmission from mother to child (32–34). Silverberg showed that children born to mothers with active condylomata had a 231-fold increased risk of developing RRP when compared to children born to disease-free mothers (35). In addition, they showed that children born to women with active condylomata had a twofold higher risk of developing RRP if labor lasted more than 10 hours. Kashima found that childhood-onset RRP patients were more likely to be first born and vaginally delivered than were control patients of similar age (36). The authors hypothesized that primagravid mothers are more likely to have a long second stage of labor and that the prolonged exposure to HPV in the birth canal leads to a higher risk of infection in the first born child. They also suggested that newly acquired genital HPV lesions are more likely to shed virus than long-standing lesions. This would explain the higher incidence of RRP observed among the offspring of young mothers of low socioeconomic status—the same group that is more likely to acquire sexually transmitted infections such as HPV.

Hallden showed that 54% of JORPP patients were born to mothers with a history of vulvar condylomata at the time of delivery (37). Despite this apparent close association, few children exposed to genital warts at birth actually develop clinical disease (38). It is not well understood why RRP develops in so few children whose mothers have condylomata. Although HPV could be recovered from the nasopharyngeal secretions of 30% of infants exposed to HPV in the birth canal the number of infants expected to manifest evidence of RRP is only a small fraction of this (39). Based on these data, it appears that secondary factors including patient immunity; timing, length, and volume of virus exposure; and local traumas (intubation, extraesophageal reflux) must be important in the development of RRP. Reports of neonatal papillomatosis suggest that, in at least some cases, development of the disease may occur *in utero*. Because caesarean section does not seem to prevent the development of RRP in all cases, a better understanding of the risk factors associated with RRP is needed before the efficacy of caesarean delivery in preventing papilloma disease can be fully assessed (40).

A case-control study found that patients with AORRP had more lifetime sexual partners and a higher frequency of oral sex than matched controls (36). This data would suggest patients with AORRP are exposed later in life than patients with JORRP. However, HPV has the disturbing capability to form latent infections in the basal cell layer of otherwise healthy appearing mucosa (16–18). It has been suggested that AORRP may represent a reactivation of HPV infection acquired during birth instead of a *de novo* exposure during adulthood.

Viral DNA has been detected in areas of "normal appearing mucosa" adjacent to papilloma lesions, suggesting a possible explanation for the recurrence of the disease following thorough surgical removal (18,38). Brandsma reported finding HPV DNA in 4% of random, clinically normal biopsies of the airway (41). AORRP, thus, could reflect either activation of virus present since birth or an infection acquired in adolescence or adult life. Nosocomial acquisition of virus by patients in the operating room

Figure 94.3 Papilloma lesions involving the trachea in a child with extralaryngeal disease.

(OR) also may result theoretically from improper equipment sterilization or room preparation. However, current Occupational Safety and Health Administration recommendations have virtually eliminated this risk.

Although any site along the upper aerodigestive tract can be affected, HPV shows a predilection to infect sites where ciliated columnar and squamous epithelia are juxtaposed (8). This explains the frequent involvement of the false vocal folds, the upper and lower margins of the ventricle, and the undersurface of the true vocal folds. In tracheotomized patients, papillomas often are encountered at the stoma and in the mid-thoracic trachea, which are areas where iatrogenic trauma to ciliated epithelium often induces squamous metaplasia (see Fig. 94.3). It is postulated that an eddying flow of the mucous blanket at squamociliary junctions may concentrate infectious viral particles at these sites. Children with bronchopulmonary dysplasia who require prolonged endotracheal intubation also may be at increased risk for development of RRP. An endotracheal tube may play the same role in the mechanical dissemination or implantation of papilloma virus as a tracheotomy in this setting, through the interruption of the continuous respiratory mucosal surface. Gastroesophageal reflux disease (GERD) also has been identified as a potential risk factor for disease persistence, although additional research is necessary to verify this anecdotal observation.

CLINICAL FEATURES

Because the most common symptoms of RRP are related to airway obstruction, it is not uncommon for children to be misdiagnosed initially as having asthma, croup, or chronic bronchitis. The hallmark of RRP in children is the triad of relentlessly progressive hoarseness, stridor, and respiratory distress. Hoarseness in children tends to be overlooked or at least accepted until it reaches a certain level of severity. However, any infant or young child with symptoms of voice change, along with obstructive airway symptoms or recurrent croup, warrants laryngoscopy to rule out neoplasia, with RRP being the most likely lesion.

Children with RRP most often present with some degree of dysphonia. Stridor is often the second clinical symptom to develop, beginning as an inspiratory noise and becoming biphasic with progression of the disease. Less commonly, chronic cough, recurrent pneumonia, failure to thrive, dyspnea, dysphagia, and acute life-threatening events may be the presenting symptoms. The duration of symptoms prior to diagnosis varies with a typical period of about 1 year from onset of symptoms till a diagnosis of RRP is made. Not uncommonly, a mistaken diagnosis of asthma, croup, allergies, vocal nodules, or bronchitis is entertained before arriving at the definitive diagnosis of RRP.

Because of the rarity of RRP and the slowly progressive nature of the disease, some cases may go unrecognized until respiratory distress results from papillomas obstructing the airway. The result is a relatively high need for tracheotomy to be performed in these children. Shapiro et al. (42) noted that RRP tracheotomy patients presented at a younger age and with more widespread disease, often involving the distal airway prior to tracheotomy. In the Centers for Disease Control and Prevention (CDC) registry, children with tracheotomy were initially diagnosed with RRP at a younger age (2.7 years) than those without a tracheotomy (3.9 years) (7). Both prolonged tracheotomy and the presence of subglottic papilloma at the time of tracheotomy have been associated with an increased risk of distal tracheal spread.

Extralaryngeal spread of respiratory papillomas has been identified in 13% to 30% of children and in 16% of adults with RRP (5,43). The most common sites of extralaryngeal spread were, in order of frequency, the oral cavity, trachea, and bronchi (5). In a recent review of the experience at three academic medical centers, 12% of the children with RRP had distal tracheal spread of their disease and 7% had pulmonary dissemination. One common thread in the children with distal spread was the use of jet ventilation anesthesia techniques in the surgical management of their disease (44). Pulmonary RRP begins as asymptomatic, peripheral nodules and progresses to enlarging lesions with central cavitation and necrosis. Pulmonary RRP is insidious and progresses over years. It can eventually manifest as respiratory failure due to destruction of the lung parenchyma and malignant transformation.

The course of RRP is variable with some patients experiencing spontaneous resolution. However, RRP is frequently characterized by relentless recurrence and most patients necessitate frequent surgical debridements. Certain patient factors such as younger age at diagnosis and HPV 11 subtype are linked to aggressive progression of RRP. A possible

link between RRP and immunodeficiency states also has been observed. Both children and adults with acquired immunodeficiency syndrome, congenital immunodeficiencies, or those on immune suppression after organ transplantation have been identified with RRP (7). Respondents in a recent American Society of Pediatric Otolaryngology (ASPO) survey related at least one death from RRP in their clinical practices (43). When death occurs, it is usually associated with a complication of frequent surgical procedures or caused by respiratory failure due to distal disease progression.

Dysplastic and malignant transformation have been reported in RRP. In a recent study by Sajan et al. (45), RRP biopsy specimens of 20 patients with JORRP were examined. Only 1 of 123 specimens (less than 1%) had evidence of dysplasia. Dysplasia in AORRP appears to be more prevalent with 22% to 55% of patients demonstrating evidence of dysplasia on histopathology (46,47). An RRP task force survey reported malignant transformation of RRP into squamous cell carcinoma (SCC) in 26 cases (43). The mechanism of RRP transformation remains poorly understood. In a recent study by Lee in which six AORRP patients developed laryngeal carcinoma, the only risk factor associated with malignant transformation was an absence of HPV DNA on polymerase chain reaction of papilloma specimens (48).

PATIENT ASSESSMENT

History

Persistent or progressive stridor and dysphonia, with the possible development of respiratory distress, are the most consistent signs and symptoms of RRP in children (Table 94.1). In the absence of severe respiratory distress, a careful history should be obtained. Information regarding the time of onset of symptoms, possible airway trauma including a history of previous intubation, and characteristics of the cry are obviously important. Hoarseness, although a common and often benign clinical complaint in young children, always indicates some abnormality of structure or function. Because of the precision of laryngeal mechanics, hoarseness may result from a remarkably small lesion and thus be an early sign in the course of a disease process. On the other hand, if the lesion's origin is remote from the vocal cords, hoarseness may present as a late sign. Although histologically the same lesion, a papilloma that produces hoarseness in one patient may produce stridor and obstruction in another, depending on the size and location of the lesion. The quality of the voice change may give only limited clues to its etiology, whereas other characteristics such as age of onset, rate of progression, associated infection, history of trauma or surgery, and the presence of respiratory or cardiac distress may be of much greater significance. A low-pitched, coarse, fluttering voice suggests a subglottic lesion, whereas a high-pitched, cracking voice, aphonia, or a breathy voice suggests a glottic lesion. Associated high-pitched stridor also suggests a glottic or subglottic lesion. Although stridor that has been present since birth is more often associated with laryngomalacia, subglottic stenosis, vocal cord paralysis, or a vascular ring, it should be realized that neonates also can present with papillomatosis.

Associated symptoms such as feeding difficulties, allergic symptoms, vocal abuse, and the presence of hereditary congenital anomalies may help distinguish RRP from alternative diagnoses, including vocal fold nodules, vocal fold paralysis, subglottic cysts, subglottic hemangioma, and subglottic stenosis. In the absence of any history suggesting these lesions, review of the perinatal period may reveal a history of maternal or paternal condylomata. If the onset of stridor and dysphonia is gradual and progressive over weeks or months, then neoplastic growth compromising the airway must be considered and investigated.

Certainly not every child with a hoarse voice or cry merits investigation beyond an assessment of the symptom. However, in the presence of hoarseness with respiratory distress, tachypnea, decreased air entry, tachycardia, cyanosis, dysphagia, chronic cough, failure to thrive, recurrent pneumonia, or dysphagia, the larynx must be visualized and a firm diagnosis of the cause of hoarseness must be made. Any child with slowly progressive hoarseness merits investigation and the clinician should not wait until total aphonia or airway problems occur.

TABLE 94.1 COMMON PRESENTING SYMPTOMS IN CHILDREN WITH RRP

Progressive hoarseness
Stridor
Increasing dyspnea

Physical Examination

Children presenting with symptoms consistent with RRP must undergo a thorough and organized physical examination. The child's respiratory rate and degree of distress must first be assessed. The physician should observe the child for tachypnea or the onset of fatigue that may indicate impending respiratory collapse. The child should be observed for flaring of the nasal ala and the use of accessory neck or chest muscles. Increasing cyanosis and air hunger may cause the child to sit with the neck hyperextended in an attempt to improve airflow. If a child is gravely ill, additional examination should not be undertaken outside the OR, the emergency room, or the intensive care unit, where resuscitation equipment for intubation of the airway, endoscopic evaluation, and possible tracheotomy are readily available.

In the stable, well-oxygenated child, additional examination can proceed. The most important part of the examination is auscultation with the aid of a stethoscope. The physician should listen over the nose, open mouth, neck, and chest to help localize the probable site of the respiratory obstruction. A useful technique is to pull the bell off the stethoscope and listen over these areas with the open tube. The respiratory cycle, which is normally composed of a shorter inspiratory phase and a longer expiratory phase, should then be observed. Stridor of a laryngeal origin is most often musical and may begin as inspiratory, but will progress to biphasic with worsening airway narrowing. Infants with stridor should be placed in various positions to elicit any changes in the stridor. A child with RRP would not be expected to demonstrate much change in the stridor with position change in contrast to infants with laryngomalacia, a vascular ring, or a mediastinal mass. Pulse oximetry can add an accurate quantitative analysis of the child's respiratory state. In the stable patient in whom asthma is a likely diagnosis, pulmonary function testing combined with arterial blood gas evaluation also may be helpful.

Airway Endoscopy

The preoperative diagnosis of RRP is best made with a flexible fiberoptic nasopharyngoscope. Careful, sequential inspection of the pharynx, hypopharynx, larynx, and subglottis provides the critical information necessary to make the diagnosis of RRP and allows estimation of lumen size, vocal cord mobility, and the urgency of operative intervention. Advances in instrumentation of flexible nasopharyngoscopes have resulted in instruments as small as 1.9 mm in diameter that allow passage in even the smallest newborns. Even the smallest diameter scopes provide images that can be seen on a video monitor and recorded for later review. Recording of sequential endoscopic examinations allows for assessment of disease progression. Topical decongestion and local anesthesia can be applied by spray, dropper, or pledget. Oxymetazoline is the decongestant of choice because of its lack of cardiac side effects. Either topical tetracaine or lidocaine may be used to enhance patient cooperation, but the dosage must be critically monitored in the small infant to avoid cardiotoxicity.

Most clinicians find that visualization with the flexible nasopharyngoscope is far superior to that obtained with indirect mirror laryngoscopy in young children. Patient cooperation, however, is required even with good topical anesthesia. In infants, this is not a large issue because they can easily be restrained in a sitting-up position in the parent's or nurse's lap for evaluation. Likewise, most patients over 6 or 7 years of age can cooperate with the examination. It is the intermediate age group, between 1 and 6 years of age, who may be the most difficult to examine, taxing the patience and skill of even the most experienced clinicians. Although dynamic evaluation may be appreciated when children are spontaneously breathing, endoscopy in the OR under anesthesia is warranted in any child suspected to have RRP who cannot be fully examined in the outpatient setting.

OTHER CONSIDERATIONS

Children newly diagnosed with RRP warrant a substantial time commitment on the part of the otolaryngologist to engage the family in a frank and open discussion of the disease and its management. Support groups such as the Recurrent Respiratory Papilloma Foundation (RRPF: www.rrpf.org; PO Box 6643 Lawrenceville, NJ 08648-0643) and the International RRP ISA (Intl RRP ISA: www.rrpwebsite.org; PO Box 30821, Seattle, WA 98113-0821) can be a vital resource for information and support.

RRP patients require frequent office visits and endoscopic procedures at the outset to establish the aggressiveness of their disease. They are encouraged to return to the office or call as often as necessary while family members and the health care team become familiar with the child's symptoms and level of distress. Although infant home intercom-type monitors are often recommended, apnea/bradycardia monitors and pulse oximetry are generally not necessary. Repeat flexible fiberoptic laryngoscopy may be used in the office setting, as may speech and language therapy if offered early in the course of the disease. Control of other medical factors such as reflux and asthma is also aggressively pursued.

SURGICAL MANAGEMENT

No single modality has been consistently effective in eradicating RRP. The current standard is surgical therapy with a goal of maintaining an airway and doing no harm. For patients with anterior commissure disease or highly aggressive papilloma, the goal may be subtotal removal to avoid excessive scarring. Overzealous surgical therapy, however, can lead to significant scar injury that can leave the patient with continued airway or vocal dysfunction once the disease goes into remission. When in doubt, it is best to leave the disease behind in the anterior commissure and interarytenoid areas because the majority of complications following disease remission are related to damage in these areas. Most patients with JORRP require repeated surgery with a median of 7 surgeries in Lindeberg and Elbrond's series, 13 surgeries in that of Morgan and Zitsch's, and 19 in Derkay (1,5,26).

Currently, there are no medical or surgical cures for RRP. Goals of any therapeutic RRP regimen include eradication of disease from the airway, improvement in voice quality, control of disease spread, and decrease in the number of trips to the OR for surgical debridement. Surgical management remains the mainstay of therapy for RRP. A balance must be achieved between returning to the OR frequently, which carries the risks of stenosis, webbing, and anesthesia, versus prolonging intervals between operative interventions.

TABLE 94.2 POTENTIAL SURGICAL MODALITIES FOR RRP

Microlaryngoscopy with cup forceps removal
Microdebrider powerized resection
CO_2 laser
KTP laser
Pulse-dye lasers

RRP, recurrent respiratory papillomatosis.

Longer intervals between procedures, however, may allow for disease spread and increasing tumor burden.

There are multiple different surgical techniques that can be utilized to treat RRP. These include the use of the microdebrider, the laser, and sharp dissection (Table 94.2). Traditionally, the CO_2 laser has been favored over cold instruments in the treatment of RRP involving the larynx, pharynx, upper trachea, and nasal and oral cavities (49). The CO_2 laser has an emission wavelength of 10,600 nm, and converts light to thermal energy. It provides a controlled destruction of tissues with vaporization of water and also cauterizes tissue surfaces. When coupled to an operating microscope, the laser vaporizes the lesion with precision while causing minimal bleeding. When used with a no-touch technique, the CO_2 laser minimizes damage to the vocal folds and limits scarring.

In recent years, the utilization of the microdebrider for endoscopic management of RRP has gained popularity. In a survey of pediatric otolaryngologists conducted in 2002, the majority of respondents (52%) identified the microdebrider as the preferred technique for papilloma removal (43). Similarly, our current surgical preference for debulking of RRP involves the use of the microdebrider. Advantages of this technique include: improved voice outcomes, minimal collateral laryngeal mucosal thermal trauma, less procedure time, fewer personnel required in the OR, reduced cost when compared to the laser, and no increase in pain scores (49–52). Safety advantages include no risk of laser fire or burns and reduced risk of exposure of OR personnel to aerosolized viral particles.

Technologic advances in fiberoptic laser delivery and endoscopy using distal-chip scopes have made office-based therapy of AORRP a viable, cost-effective option. In addition to being safe, office-based airway laser procedures are well tolerated by patients. A recent study reported 87% of patients preferred office-based laser procedures to similar OR-based upper aerodigestive tract laser procedures (53). For the most part, pediatric patients still require general anesthesia for treatment of their RRP. This is due to problems with cooperation and a smaller airway.

In the past several years, the pulse dye laser (PDL) has been gaining popularity for the treatment of RRP, and it is now recognized as a viable treatment option. Patients with sessile lesions, disease involving the ventricle, and areas with the potential for significant scarring may benefit from the use of the PDL. The PDL is a nonablative laser that selectively targets the microvasculature of the lesion, thus sparing the epithelium, a photoangiolytic effect. The wavelength of the PDL is 585 nm. The PDL takes advantage of the chromophore in oxyhemoglobin, which has peaks at both 540 and 585 nm (54).

The PDL can be employed in either the OR or in an office-based setting. Hartnick et al. demonstrated that the 585 nm PDL was safe and effective for use in RRP in the pediatric population. In their small (n = 23), prospective, longitudinal study, they noted no events of anterior commissure webbing or true vocal cord scarring on lesions treated with the PDL. Additionally, they found no evidence of damage to the normal epithelium during PDL therapy. This finding would allow bilateral anterior commissure therapy to be performed during one surgery and could potentially lead to improved voice outcomes. They also commented that the flexible fiberoptic delivery of PDL energy made it advantageous for lesions in hard-to-treat locations including the ventricles, infraglottic area, and trachea (55). Koufman and Mouadeb promote the effectiveness of the PDL in the office setting (56,57). Using little to no topical anesthesia, Koufman's group performed 212 PDL procedures on 59 RRP patients with an average of 3.6 procedures per patient and a mean follow-up of 17 months. They noted no complications associated with the PDL procedures. Mouadeb performed office-based PDL therapy on 21 RRP patients with similar results of no anterior glottic webbing or vocal cord scarring. Additionally, they noted a statistically significant improvement in Voice Handicap Index (VHI) on the patients in their study.

Thus, PDL promises to be a part of our expanding armamentarium for JORRP and AORRP. With current third-party reimbursement rates, there are perverse financial disincentives preventing the widespread utilization of office-based PDL therapy for RRP. Rees et al. found a potential $5,000 per case savings when PDL therapy was performed in the office instead of under general anesthesia, yet the existing reimbursement scheme does not cover the cost for the surgeon of using the laser in the office. Until there is reconciliation of the cost-payment issues, this office-based technology and its benefits will be largely unavailable to RRP sufferers (58).

Two other lasers that can be delivered via a flexible fiberoptic medium for treatment of RRP are the pulsed potassium-titanyl-phosphate (KTP) laser and the flexible CO_2 laser. The KTP laser has a wavelength of 532 nm, which is similar to one of the peak absorption wavelengths of hemoglobin. The KTP laser can be used in either the office or the OR setting to treat papillomatous lesions in a similar, photoangiolytic, fashion to the PDL. Burns conducted a prospective pilot study of the KTP laser in 55 AORRP patients using disease regression as a primary endpoint (54). At least 90% disease regression was achieved in 80% of AORRP patients. Despite having 93% of their

cases with anterior commissure disease, they reported no new webbing. The authors prefer the KTP laser to the PDL because of the extended pulse width of the KTP. This extended pulse width allows for enhanced clinical efficacy and uses a wavelength closer to an absorption peak of oxyhemoglobin (54). No study yet has determined the optimum energy delivery necessary to affect tissue coagulation and/or effectively cause photoangiolysis (59).

The flexible CO_2 laser allows access to previously difficult to reach areas including the trachea, tongue base, and hypopharynx. This laser uses a hollow core fiber that allows passage of both the laser beam and nitrogen flow for cooling. It enables the surgeon to change focus and intensity manually without adjusting a micromanipulator. The fibers are only 1.8 mm in diameter and fit easily through the suction port of both a ventilating bronchoscope and a Lindholm microlaryngoscope. Additionally, the CO_2 laser fiber can be used with a variety of angled handpieces that allow access to the oral and nasal cavities.

SPECIAL CONSIDERATION

Surgical management of RRP is challenging. Whenever possible, utilize the most-experienced pediatric-trained anesthesiologist and OR staff available.

Tracheotomy is occasionally used as an alternative or an adjuvant to repeated endoscopic surgery. However, it has been suggested that tracheotomy may activate or spread disease lower in the respiratory tract. Cole reported on the Cincinnati Children's Hospital JORRP experience in which tracheal papillomas developed in half of their tracheotomy patients. Despite attempts to avoid this procedure, 21% of their patients still required a long-term tracheotomy (60). Shapiro, on the other hand, described a favorable experience with the placement of tracheotomies in children with JORRP treated at the Children's Hospital of Pittsburgh (61). While 37% of the patients in this study required a tracheotomy, the presence of the tracheotomy did not change the incidence of extralaryngeal spread of disease. Most clinicians agree that tracheotomy is a procedure to be avoided in RRP patients unless absolutely necessary. When a tracheotomy is unavoidable, decannulation should be considered as soon as the disease is managed effectively with endoscopic techniques.

Recurrent Respiratory Papillomatosis Surgery

Current procedures for managing papilloma disease in the larynx with the microdebrider will be described; we will then briefly review our CO_2 laser technique. These techniques are modified depending on the location of the disease, the amount of previous laryngeal surgery, and the degree of airway obstruction. In some circumstances, papillomas may best be removed with the use of the microdebrider, in others the CO_2 or KTP laser via the ventilating bronchoscope. When determining which surgical procedure will be utilized, consideration must also be given to which anesthetic technique will be employed. When using the laser, the operating surgeon may choose to intubate the patient with a laser-safe endotracheal tube. Alternatives to this approach of securing the airway include apneic technique without intubation, insufflation techniques, or the use of jet ventilation.

Preoperative Planning

Regardless of the technique planned for removal, before the child enters the operating suite, the surgeon, anesthesiologist, and OR team must select the proper size endotracheal tubes, laryngoscopes, and bronchoscopes and ascertain that all ancillary equipment, including telescopes, light cords, suction tips, and forceps are available. The surgeon, along with the OR team, should check that all equipment used for the procedure, including the surgical microscope with appropriate size lens, the laser or microdebrider unit, the micromanipulator, filtered suction, and smoke evacuation units, are all properly functioning. In our institution, if the laser is going to be utilized, the surgeon personally checks the laser for beam alignment by test-firing it prior to the child entering the room. Laser safety is carefully monitored in our institution by the laser safety committee. This includes a laser safety officer, a physician for each specialty that uses the laser, nurses from the OR, a hospital administrator, and biomedical engineer. All OR personnel are required to wear eye protection whenever working around the laser. Specially designed laser masks are required to be worn by OR personnel during the surgery to prevent the inhalation of viral particles liberated during the laser procedure.

Before the institution of any anesthesia, the surgeon should discuss the pathology with the anesthesiologist. The ultimate decision about the technique of anesthesia, whether to use an endotracheal tube or to use a total intravenous technique (apnic or spontaneous ventilation), should be shared between the anesthesiologist and the surgeon. When the child's pathology permits, we prefer the total intravenous technique with propofol. In this technique, there is no endotracheal tube to limit access to the papillomatous lesions and to distort laryngeal anatomy. If the laser is going to be utilized, the smallest possible laser-safe endotracheal tube that allows for adequate ventilation should be used. If a cuffed tube is necessary, then the cuff should be filled with saline so that, if it is inadvertently struck by the laser beam, the saline acts as a heat sink and fire extinguisher. Some surgeons prefer to use methylene blue in saline to provide an additional warning in case the cuff is penetrated.

The majority of pediatric anesthesiologists at children's hospitals are familiar with papilloma surgery in children. However, in institutions where there are a limited number of anesthesiologists experienced in pediatric papilloma surgery, then whenever possible these individuals should be involved. This type of surgery is not well suited to the

novice surgeon, anesthesiologist, or OR nurse. It is our practice to insist that the attending anesthesiologist be present and involved "hands on" with all critical portions of the surgical procedure, including induction, changing of anesthesia techniques from an endotracheal tube to apnea technique, and extubation. We try to avoid the use of premedications and insist on having the bronchoscopes and laryngoscopes set up in advance in case the child develops airway obstruction or experiences a laryngospasm on anesthesia induction.

To this end, the staff within the OR also should be informed of the surgeon's concerns so that appropriate instrumentation is ready. When performing surgery for RRP, it is advisable to have an experienced team of OR nurses familiar with the sequence in which equipment is used. Intraoperative teamwork is enhanced with the availability of video monitors during the operation because this allows the entire OR staff to follow the operation as it progresses. Dialogue between the surgeon, nursing staff, and the anesthesiologist continues throughout the procedure regarding the current status of ventilation, the amount of bleeding encountered, the motion of the vocal cords, the timing of laser use in conjunction with respiration, and the concentration of oxygen in the anesthesia mix.

Operative Technique—Endoscopic Microdebrider

When comparing the removal of papillomas with the microdebrider and with the CO_2 laser, many of the steps are similar. We will highlight the major differences between these two techniques. When the microdebrider is used, there is a need for one less person on the OR team; the laser nurse. Likewise, all of the precautions described below regarding laser safety and aerosolizing or disseminating of HPV particles do not apply. Additionally, the anesthesia provider is not required to keep the FiO_2 below 40% which may minimize patient desaturation during the procedure.

The typical room setup includes a suspension microlaryngoscope (Lindholm), a full set of Parson laryngoscopes (Karl Storz Endoscopy America, Culver City, CA), two appropriately sized ventilating bronchoscopes, and a 7,200-A Hopkins rod telescope (Karl Storz Endoscopy America, Culver City, CA). The microscope is fitted with a 400-mm lens. An assortment of suctions, alligators, cup forceps, and light cords, as well as a pack of neuropathies and topical oxymetazoline, are also standard. An endoscopy video cart equipped with color television monitor, digital recorder, photo printer, three-chip camera, and xenon light source is also used. Additionally, a pediatric tracheotomy set is brought into the room, although the pack is not opened.

In conjunction with the nursing staff, a proper length laryngeal Skimmer blade is chosen (18 cm vs. 22 cm depending on the relative size of the child), and the microdebrider unit is typically set at between 600 and 1,000 rpm on oscillation mode.

After informed consent has been obtained from the appropriate caregivers, the child is brought to the OR that has been prepared and inspected by the surgeon. Time-out and surgical marking procedures are followed in our hospital for all OR cases. The surgical sequence begins with an anesthetic mask induction using sevoflurane and the establishment of intravenous access. Dexamethasone at 0.25 to 0.5 mg/kg is routinely administered perioperatively. The larynx is exposed using the Parsons laryngoscope attached to 6 L/min of oxygen flow through the insufflation port. The vocal folds are then sprayed with a weight appropriate dose of 2% lidocaine using a syringe attached to a Cass needle. A diagnostic laryngoscopy is performed using the 7,200-A telescope under video control to assess the degree of papilloma disease and its encroachment on the laryngeal airway. Depending on the extent of disease, the child's history, and the interval since the last endoscopy, a full tracheoscopy, and bronchoscopy also may be performed. Again, depending on the child's level of preoperative and operative distress, the surgeon may choose to perform this maneuver with either the 7,200-A telescope (if there is a low likelihood of discovering distal disease) or with an appropriate size ventilating bronchoscope (if there is high likelihood of discovering distal disease). Still photography with the 7,200-A telescope is then performed at this stage in the procedure. Photographs are useful in documenting disease extent and can be printed for inclusion in the medical record and for discussions with the family.

Once the airway has been assessed, either an endotracheal tube will be placed by the surgeon or an apneic technique with intravenous propofol and insufflated sevoflurane will be adopted. The Lindholm microlaryngoscope is then inserted and positioned. We prefer to suspend the microlaryngoscope to a Mayo stand attached to the OR table. This device allows the microsuspension system to be moved along with the patient and also allows for angulation of the laryngoscope over a 120-degree range. If a biopsy specimen is desired, we generally begin the surgery by obtaining this from the bulkiest portion of the papilloma and then apply a neuropathy soaked in oxymetazoline to the biopsy site to minimize bleeding. We prefer to operate under the highest magnification available with the light source turned to the maximal setting. It is advisable to attach the microscope camera to the video monitor so that all OR personnel, including the anesthesia team, can follow the progress of the surgery. Our preference is to begin debriding the papillomas in the supraglottis first and then work our way toward the true vocal cords. The surgeon must be comfortable working with the microdebrider in either hand; the removal of papilloma from the left side of the larynx is best accomplished when the device is used in the right hand, while disease from the right side should be removed with the microdebrider in the surgeon's left hand. The hand opposite of the device holds a microsuction

which is used to help retract tissue and evacuate blood. In order to minimize the risk of web formation, it is essential to avoid creating opposing, raw surfaces at both the anterior and posterior commissure with the microdebrider. Care should also be taken when removing sessile papillomas from the true vocal cord surface, erring on the side of leaving disease as opposed to sacrificing a portion of the vocal fold. The microdebrider does allow for removal of papillomas in the subglottis and proximal one-third of the trachea by placing a 7,200-A telescope in one hand and the microdebrider in the other.

Because of the relative increased speed in removing of the papillomas with the microdebrider technique, the entire procedure typically takes less than 45 minutes. Humidified air and occasionally, racemic epinephrine are administered postoperatively in the recovery room. The patient is then closely monitored for several hours prior to discharge, and occasionally an overnight stay in a monitored bed unit is necessary. As a general rule, the more extensive the papilloma disease and the more compromised the airway, the more important it is for the child to be monitored postoperatively in an intensive care or step-down unit. Additional doses of steroids can be administered at 6-hour intervals if needed, and continuous pulse oximetry is mandatory.

Operative Technique—CO_2 Laser

Many of the steps described above in the microdebrider technique also apply when utilizing the CO_2 laser. When performing laser surgery for RRP, it is advisable to have an experienced team of OR nurses familiar with the sequence in which equipment is used and instructed in the proper use of the laser. In our facility, we also have a laser safety team that provides yearly updates for the OR staff to ensure everyone's familiarity with the equipment and its potential complications. The laser team consists of a scrub nurse, a circulating nurse, and a laser nurse. The laser is the responsibility of the laser nurse, allowing the circulator and scrub nurse to concentrate on their duties. All OR personnel are equipped with micropore laser filtration masks and approved goggles. All equipment is set up in advance including fitting the microscope with the CO_2 laser attachment and the laser is pretested before the child enters the room to assure its alignment.

After informed consent has been obtained from the appropriate family members, including a discussion regarding potential laser complications, the child is brought back into an OR that has been prepared and inspected by the surgeon and the laser team. If the extent of disease is such that an endotracheal tube will initially be utilized to secure the airway, then the surgeon begins by intubating with a laser-safe tube (metal Xomed-Treace, Medtronics, Minneapolis) of the smallest caliber that will allow the anesthesiologist adequate ventilation. (Commercially available laser-safe tubes are preferable to aluminum-wrapped red rubber tubes.) Once the airway has been secured with the endotracheal tube, then the anesthesiologist has the option to administer muscle relaxants. However, it is often preferable to use continuous or intermittent propofol infusions to keep the child anesthetized during the procedure. It should be stressed that no muscle relaxants are administered until the surgeon has assessed the degree of laryngeal obstruction and secured the airway. This precaution serves to prevent the situation in which the child obstructs his/her airway due to papilloma, blood, or mucus, precipitating hypoxia and possible laryngospasm.

Once the airway has been secured, the endotracheal tube is anchored in place with a single piece of tape (allowing the surgeon easy access for removal of the endotracheal tube in the case of an airway fire). The child is then placed in suspension using the microlaryngoscope. Lubricant is placed in the patient's eyes. The child is further protected against laser beam exposure by placing moist, saline-soaked gauze pads over the eyes. Next, the operative field is draped with moistened towels. The surgeon confirms that all OR personnel are equipped with ocular protection, including side shields. A sign is posted outside the OR warning that a laser procedure is in progress and a spare set of safety glasses is left outside the door for OR personnel who wish to come inside the room while the laser is in operation. Special laser masks with extremely small pores are worn to minimize exposure to the laser plume. A high-volume smoke evacuator is attached to one port of the microlaryngoscope to collect the laser plume. A second suction attached to the smoke evacuator is used by the surgeon. By this point, the inspired FiO_2 delivered to the patient should be as close to a room-air mixture as possible. Ideally, the laser is not used until the oxygen in the mixture is between 26% and 30%. In selected circumstances, it may be warranted to proceed with an FiO_2 at or below 40%. These precautions are taken to minimize the possibility of a laser-induced endotracheal tube fire.

As an initial procedure, a microcup forceps is used to obtain a biopsy specimen from the bulkiest portion of papilloma. The CO_2 laser, delivered via a micromanipulator attached to the operating microscope at initial settings of 4 W power, 0.1-second intervals, and repeat mode, is then used to remove papilloma lesions. Moistened neuropathies are placed at the laryngeal inlet to decrease the air leak and to provide a backstop for errant laser shots. (These must be kept moist because they too can act as a source of combustion.) Bulky papilloma is handled by defocusing the laser. With the laser refocused, lesions are gradually vaporized to the level of the mucosa, avoiding entry into Reinke space and the deeper vocalis muscle. During papilloma removal, we prefer using low-power laser settings to limit thermal injury to the surrounding tissue, although this technique may prolong operating time. A small-caliber suction device is kept close to the laser impact site to remove the hot steam of vaporization. The suction can also be used to remove eschar and as a retractor of the vocal folds to allow for exposure of the subglottic

region. Neuropathies soaked in neosynephrine are used for both removal of eschar and debris and hemostasis. Care is taken to avoid injuring the anterior commissure, and at least 1 mm of untreated mucosa should be left in this region so that a web does not develop during the healing period. Similar precautions are taken when addressing the posterior commissure.

Papillomas in the supraglottic larynx are addressed first, by disease involving the anterior half of the true vocal cords. Surgical access to papilloma in the posterior glottis or subglottis is often obstructed by the endotracheal tube and thus an alternative means of anesthesia is sought. We prefer an apneic or spontaneous respiration technique with insufflation of oxygen and sevoflurane while the endotracheal tube is removed intermittently. An alternative technique is the use of jet ventilation.

Once a decision is made to utilize the apnea technique, the anesthesiologist increases the FiO_2 to 100%. The child is extubated but left in suspension, and the smoke evacuation port of the microlaryngoscope is disconnected. Oxygen tubing is then connected to the microlaryngoscope port to initiate flow of 6 L/min of oxygen. The carbon dioxide and oxygen levels are closely monitored and the length of "laser on" time is adjusted appropriately. The laser is used for 2- to 6-minute intervals and the child is periodically reintubated with a polyvinyl chloride endotracheal tube directly through the microlaryngoscope. (A stylet is useful to stiffen the tube and improve the angulation during intubation.) Typically, the child is reoxygenated for the same period of time that he or she was apneic before proceeding with the next laser cycle. At the end of the case, the child is then reintubated with a standard endotracheal tube using a Selinger technique to avoid any difficulty in reestablishing the airway upon removal of the microlaryngoscope. The child is extubated only when fully awake.

An alternative anesthetic technique that can be utilized during laser removal of laryngeal papillomas is jet ventilation. Jet ventilation eliminates the potential fire hazard of the endotracheal tube and allows good visualization of the vocal cords. The jet cannula can be placed either above or below the vocal cords. We prefer placement of the cannula proximal to the end of the laryngoscope to decrease the risk of possible pneumothorax or pneumomediastinum. With large laryngeal lesions, narrowed airways, and ball-valve lesions, a high degree of outflow obstruction may develop that could lead to increased intrathoracic pressure and a subsequent pneumothorax. These complications can also occur if there is inadequate muscle relaxation. Additional limitations of this technique are the possibility of transmission of HPV particles into the distal airway, excessive mucosal drying, and insufflation of air into the stomach causing gastric distention. Thus, jet ventilation requires constant communication between the operating surgeon and the anesthesiologist.

Potential complications of laser surgery include the development of anterior commissure webs, laryngeal and subglottic stenosis, burns to the patient or OR personnel, and laser-induced endotracheal tube fire. A laser fire is more likely to occur in the setting of high oxygen concentrations and in the presence of a polyvinyl chloride endotracheal tube. Direct thermal injury to local tissues or a chemical burn may result from such a mishap. In order to prevent a laser fire, the oxygen concentration should be limited to less than 40%, or alternately the patient can be ventilated with room air. In the event of a laser fire, emergency care consists of immediate extubation of the patient and disconnection of the tube from its oxygen source. The child is then reintubated and examined through a ventilating bronchoscope. Antibiotics are given and a tracheotomy may be necessary based on the degree of damage. Tertiary care consists of positive end expiratory pressure and reverse isolation.

POSTOPERATIVE CARE

Children with stable papilloma disease requiring fewer than four laser procedures per year and whose caregivers reliably follow-up prior to the child showing signs of respiratory distress can be monitored at home with commercially available infant home intercom-type monitors. Patients with rapidly reforming papillomas and those whose caregivers wait until the child is in distress before seeking medical attention may warrant home pulse oximetry with frequent home health visits. Children with RRP are encouraged to return to the office or call as often as necessary. We give them "carte blanche" within our practice and explain to them that their children have a special problem that allows them access to speak with the doctors and nurses and come to the office whenever they feel their child is in need. We have yet to experience a family that has abused this privilege. Instead, this policy has enhanced the family's trust in the health care team and has decreased the need for urgent and emergent laser procedures.

RECURRENT RESPIRATORY PAPILLOMATOSIS STAGING

A staging system for RRP is essential. Such systems are useful when tracking a child's disease progression, communicating with other surgeons, and treating patients in a protocol or study format. Although several scoring and staging systems have been proposed, clinicians have yet to adopt a uniformly acceptable nomenclature for describing RRP lesions that is both simple and comprehensive. Failure to adopt such a system has created confusion in the RRP literature and in physician-to-physician communications regarding patient's response to therapies. In addition, the absence of an accepted staging system has hampered our abilities to accurately document the natural course of the disease and to report the results of adjuvant treatments. We have proposed a severity/staging system for RRP in a format that incorporates the best qualities of the existing systems by numerically grading the extent of papillomatosis at defined aerodigestive

subsites. The staging system also assesses functional parameters, diagrammatically catalogs subsite involvement, and assigns a final numeric score to the patient's current extent of disease (Fig. 94.4) (62). Using software designed at the University of Washington (Seattle) and licensed to the ASPO, this staging system is now computerized and available to pediatric otolaryngologists and bronchoesophagologists to allow them to objectively and subjectively measure an individual patient's clinical course and response to therapy over time. Encryption technology with this software offers promise to allow clinicians from around the world to anonymously share some of their patient data in a HIPPA-compliant format to enhance our knowledge of this disease and promote multi-institutional investigations.

MEDICAL MANAGEMENT

Though surgical management remains the mainstay of therapy for RRP, ultimately more than 20% of patients with the disease require some form of adjuvant therapy (43) (Table 94.3). The most widely adopted criteria for initiating adjuvant therapy are a requirement of more than four surgical procedures per year, distal or metastatic disease, and/or rapid regrowth of papilloma disease with airway compromise (63).

ADJUVANT THERAPIES

The most commonly utilized adjuvant medical therapy for RRP is intra-lesional cidofovir (Vistide) (43). Cidofovir is a nucleoside analog of deoxycytidine monophosphate. Once converted to its active form, this prodrug becomes incorporated into DNA and produces toxicity against the herpes virus family. It is FDA approved only for intravenous use in the treatment of cytomegalovirus retinitis in patients with HIV. However, laboratory and clinical studies have demonstrated its effectiveness in the intralesional treatment of RRP in adults and children (64–66). Cidofovir is relatively widely used "off label" for severely affected RRP patients (43). When we utilize cidofovir, our approach is to inject 5 mg/mL into the papilloma bed after microdebriding to a total volume of 2 mL and will commit to repeating this procedure at 4- to 6-week intervals for up to 6 months.

Chadha performed a 10-year systematic review of the literature regarding RRP treated with intralesional cidofovir and reported complete disease resolution in 57% of patients and a partial response in 35% of patients. Despite these promising numbers, the authors note a tremendous variability in dosage, interval of administration, and number of injections. They also point out the need for a well-designed, placebo-controlled, double-blinded, randomized trial to better study this adjunct (67). In contrast, McMurray found no statistical difference when comparing cidofovir and placebo RRP treatment groups. Both arms of the study showed statistically significant improvements in Derkay severity score, VHI, and a quality of life. Limitations of this study include a small sample size (n = 19), low dose of cidofovir (0.3 to 5 mg/mL), and a short follow-up period (68). Despite its weaknesses, this study highlights the importance of the placebo group in demonstrating the effectiveness of surgical debridement in the successful treatment of aggressive RRP. Donne's recent work provides additional insight into the variable responses described when using intralesional cidofovir in RRP patients. The authors found that while cidofovir was effective against HPV 16 infected cells, it had only marginal effectiveness against HPV 6 infected cells. This study was performed in

RRP, recurrent respiratory papillomatosis.

an isogenic system in which low- and high-risk viral proteins are expressed in the same genetic background. The authors concluded that cidofovir might have little selectivity for low-risk HPV (type 6)-related disease (69).

Based upon animal toxicity studies and case reports, there are concerns regarding the side-effect profile of cidofovir including the induction of dysplasia and malignant degeneration of papilloma lesions following intralesional injection (51). Naiman et al. (70) looked at cidofovir plasma concentrations after intralesional airway injection in patients with RRP. They found that intralesionally injected cidofovir was absorbed to some degree in the bloodstream. Of 35 patients (adults and children), one adult reached levels at the upper end of recommended therapeutic levels to prevent nephrotoxicity. During a 26-week intravenous toxicology study in rats, similar levels of cidofovir were shown to cause a significant increase in mammary adenocarcinomas (71). However, Lacy et al. (72) showed that no tumors were detected in cynomolgus monkeys who were injected with intravenous cidofovir (with and without oral probenecid) once weekly over a 52-week period. In a thorough review of the side effects of cidofovir in RRP, Broekema identified 31 articles meeting the inclusion criteria (73). The results showed that dysplasia occurred in 2.7% of all patients treated with intralesional cidofovir. This percentage is concurrent with the reported incidence of spontaneous malignant degeneration of RRP (2.3%). They concluded that intralesional cidofovir use in RRP does not increase the risk of laryngeal dysplasia. Lindsay reported on a retrospective review of pediatric operative biopsy specimens from JORRP patients treated with cidofovir and found no cases of dysplasia identified in those specimens (74).

Until additional studies have been performed demonstrating its safety, it is our opinion that use of cidofovir in RRP follows the recommendations of the Task Force on RRP (51) listed below:

I. Given the promising results reported in pediatric and adult patients, cidofovir should be routinely presented as a treatment option in moderately-to-severely afflicted RRP patients, that is, those patients whose disease is not improving on surgical therapy alone or in conjunction with less potentially morbid adjuvant measures and/or requiring surgical intervention greater than three times a year.
II. With appropriate consent, cidofovir therapy should be a viable option in patients whose disease severity is resulting in a need for frequent surgery, worsening airway compromise, severely impaired communication, or those who otherwise may be considered candidates for tracheotomy.
III. Patients with more mild disease, particularly children, should be discouraged in most cases from seeking treatment with cidofovir, until a better understanding of the long-term implications of the use of this drug have been established. With appropriate informed consent, cidofovir could still be utilized on a case-by-case basis, at the discretion of the prescribing physician, for the more mildly affected patient.
IV. As with all surgical procedures, informed consent should be obtained and documented in the patient's record. At a minimum, this should include a frank discussion of the nephrotoxic and carcinogenic potential of this drug: limiting usage of adjuvant cidofovir to treatment in only severe or recalcitrant cases in children.

When a decision has been reached to begin a trial of cidofovir, we recommend administering the drug at the 5 mg/mL concentration as an intralesional injection following debridement of papillomas. The authors usually try to avoid using more than 2 mL during a single procedure. Administration may be repeated at 4- to 6-week intervals for a 6-month trial period. The trial can be abandoned if no demonstrable clinical benefit is achieved after this time interval.

Celecoxib (Celebrex)

Recent research into the molecular biology of RRP, specifically the signaling cascades leading to regulation of cyclooxygenase-2 (COX-2), has revealed that HPV-infected cells behave differently. The individual elements of these unique signaling cascades may present themselves as new targets for therapeutic regimens in the treatment of RRP and other HPV-induced diseases (75). Favorable anecdotal results with the use of Celecoxib (Celebrex) have resulted in the initiation of a multi-institutional study of COX-2 inhibitors in the treatment of adults and children with RRP.

Interferon

Interferon has been used as an adjuvant therapy in patients with RRP since the 1980s. In addition to being one of the initial adjuvant therapies, interferon was formerly the most common adjuvant therapy for treatment of RRP. Interferons are a class of proteins manufactured by cells in response to a variety of stimuli, including viral infection. The exact mechanism of action is unknown, but interferon is thought to inhibit viral protein synthesis by modulating the host

immune response (76). In 1995, 9% of children with RRP received the drug, and the most recent survey of pediatric otolaryngologists demonstrates its use has been cut to less than 4% (5,43). This decline in the use of interferon as an adjuvant treatment for RRP is due to several factors, including the high side-effect profile and the emergence of cidofovir. The most frequently utilized product, recombinant alpha-interferon (Roferon, Roche), has recently been taken off the market and replaced by peginterferon alfa-2a (Pegasys, Roche). A special strand called a "peg" has been attached to this interferon molecule to increase the half-life of the drug. Once attached, the peg helps protect the interferon from being destroyed by the host immune system. In addition to increased effectiveness, peginterferon alfa-2a also has a better safety profile and a simpler dosing regimen. The newer formulation needs to be administered only once weekly by subcutaneous injection.

The side-effect profile of alpha-interferon is multifarious and includes both acute and chronic reactions. The acute reactions are fever and generalized flu-like symptoms as well as nausea and vomiting. They tend to subside with prolonged therapy. Chronically, interferon can cause growth retardation in children, elevated liver enzymes, alterations in the central nervous system (leukopenia spastic diplegia), febrile seizures, and thrombocytopenia. Rashes, dry skin, alopecia, pruritis, and fatigue are also possible. Most side effects are short term and do not necessitate cancellation of therapy (77,78).

Long-term efficacy of interferon therapy was recently evaluated in a multicenter, nonrandomized prospective series by Gerein (78). The authors found that 63% of patients (with active disease and surgery-free interval less than 3 months) had macroscopic remission at the end of long-term interferon therapy. Even in the group of nonresponders, the majority of patients had an increased surgery-free interval. However, after long-term follow-up of 172 months, only 42% of patients were in complete remission. Gerein also noted a statistically significant difference in responses based upon HPV subtype, with 68% of patients with HPV 6 remaining in remission at the end of the follow-up in contrast to only 18% of patients with HPV 18.

Antireflux Therapy

The relationship of RRP and GERD has been discussed in the literature for well over a decade (23,79,80). It is known that recurrent or chronic exposure to acid and gastric enzymes can cause inflammatory changes to the epithelial lining of the aerodigestive tract. This local inflammatory change may play a role in determining the outcome for an individual patient whose larynx has been exposed to HPV. A recent case series demonstrated treatment of GERD in RRP patients with resistant disease resulted in improved outcomes (79). The authors showed either complete or partial response of RRP in four children when reflux was controlled with either medical management (medication and diet) or in one case, fundoplication. Furthermore, when compliance with reflux therapy waned in three of the patients, the RRP returned. Restarting medical management again resulted in improved RRP disease control. Other authors have reported similar findings. Holland et al. (23), in a retrospective review of JORRP patients, found that "high-risk patients" (defined as higher chance of developing complications due to increased trips to the OR for disease control) who were treated with antireflux therapy were significantly less likely to form laryngeal webs than those without reflux therapy.

Indole-3-Carbinol

Indole-3-carbinol is an over-the-counter nutritional supplement found in high concentrations in cruciferous vegetables like broccoli, cabbage, brussels sprouts, and cauliflower. It is a potent inducer of cytochrome P450-regulated metabolism of estrogen. Estrogen is important in RRP because it increases HPV gene expression allowing for epithelial proliferation (81,82). A study on immune-compromised mice receiving transplanted HPV-infected laryngeal tissue demonstrated nearly a 75% reduction in the formation of papilloma tumors when given indole-3-carbinol (83). Rosen et al. (84) performed a long-term (mean 56.7 months), open-label, prospective study using indole-3-carbinol for the treatment of RRP in adults and children. The authors found either complete or partial response in 70% of the patients. In the trial, pediatric patients did not respond as well to indole-3-carbinol as adults. Larger studies are necessary to further elucidate questions regarding this therapy.

Therapeutic Vaccination—HSPE7

Preliminary research into the development of therapeutic HPV vaccines is focusing on utilizing early viral proteins such as E6 and E7 as the target antigen. One such drug is HspE7, a recombinant fusion protein consisting of 638 amino acids derived from *Mycobacterium bovis* bacilli Calmette-Guerin heat shock protein 65 (Hsp65) covalently linked at its C terminus to the E7 protein of HPV type 16 (HPV 16). The HspE7 protein is produced in *Escherichia coli* expression strain BLR (DE3). Injection of HspE7 in animal studies results in specific humoral and cell-mediated immune responses leading to regression of epithelial cell-derived tumor. Administered subcutaneously in clinical trials, it has been shown to be effective against genital warts in women and girls, not only with HPV 16 but also in non–HPV-16 strains suggesting cross-reactivity. Phase II study results in an open-labeled trial demonstrated that over a 14-month period, the intersurgical interval doubled in almost half the patients and the absolute number of surgeries decreased significantly (85). As a systemic immune modulator, HspE7 has a low side-effect profile, and its

administration can be done in the outpatient setting making it an attractive choice. Larger, placebo-controlled, blinded, phase III trials will be needed to confirm the effectiveness of HspE7. However, manufacturing concerns are currently delaying the regulatory process.

Bevacizumab (Avastin)

Avastin is an angiogenesis inhibitor drug that, when combined with the 532 nm flash-dye laser, may have a significant effect on recurrent respiratory papillomas. In an open-label study involving 10 adult patients, Zeitels demonstrated a 90% reduction in recurrence after five treatments (injections followed by KTP laser) (86). A phase I single center open-labeled study to assess safety and tolerability in 20 adult RRP patients is currently recruiting subjects. Researchers are also contemplating a clinical trial in pediatric RRP patients involving systemic propranolol (inderal) because of its antiangiogenesis properties.

Artemisinin and its related compound artesunate are antimalarial drugs that have shown a therapeutic benefit on canine papillomavirus. These drugs induce apoptosis and have antiangiogenic activity. Limited data are currently available regarding its benefits in RRP patients.

Preventative Vaccination—Quadrivalent HPV Vaccine

The most interesting and promising recent development in the prevention of RRP is the quadrivalent HPV vaccine (GARDASIL, Merck and Co., Inc.). This vaccine is currently licensed by the FDA for the prevention of cervical cancer, adenocarcinoma *in situ*, and intraepithelial neoplasia grades 1 to 3; vulvar and vaginal intraepithelial neoplasias grades 2 to 3; and genital warts associated with HPV 6, 11, 16, and 18 (87). HPV types 16 and 18 cause approximately 70% of cervical cancers worldwide, while HPV types 6 and 11 cause more than 95% of genital warts. The future II study group performed a randomized, double-blind trial in 12,167 women between 15 and 26 years to receive either three doses of a quadrivalent vaccine against HPV 6, 11, 16, and 18 or placebo to evaluate prevention of high-grade cervical lesions (87). The women were followed for 3 years after receiving their first vaccine dose and achieved a 98% efficacy for prevention of high-grade cervical lesions. Based upon this phase III study and several well-designed phase II studies the United States Center for Disease Control (CDC) Advisory Committee on Immunization Practices has recommended vaccination for all girls aged 11 to 12, girls and women aged 13 to 26 who have not yet been vaccinated, and girls as young as age 9, where the physician feels it would be appropriate (88,89). Recently, the FDA has also approved its use in boys aged 9 through 25. The vaccine is predicted to reduce the incidence, morbidity, and mortality of cervicovaginal HPV disease. Based on the above recommendations, numerous countries have passed laws to educate the public and encourage use of the vaccine, but few states in the United States have mandated vaccination (90).

Unfortunately, Hildesheim found that the bivalent vaccine had a lack of efficacy as a therapeutic vaccine (91). In a trial involving 7,000 18- to 25-year-old Costa Rican women, the authors demonstrated no effect of the vaccine on viral clearance. In an editorial published in the same issue of *JAMA*, Markowitz highlights the implications of this study (92). Specifically, she emphasized the need for continued Pap screening and post-licensure safety monitoring. Additionally, she discussed the potential for the vaccine to still benefit women with existing HPV infection with one virus type by boosting the antibody response and increased protection from infection by other HPV vaccine types. An added, and often overlooked, benefit of near universal vaccination may be a concomitant decrease in thwe incidence of RRP in all age groups.

There is also a large body of evidence surrounding the role of HPV infection in the development of head and neck SCC. The overall HPV prevalence in head and neck SCC is estimated at 26% with higher prevalence in oropharyngeal SCC (36%) than in oral (24%) or laryngeal (24%) SCC. Tonsillar SCC has the highest rate of HPV detection at 51%, which makes this anatomic location the highest of any extragenital malignancy (93). D'Souza et al. (94) performed a case-controlled epidemiologic study, which showed a strong association of oropharyngeal cancer and HPV. They found HPV 16 DNA in 72% of the tumor specimens from their enrolled oropharyngeal cancer patients. Nearly 30,000 new cases of oral and oropharyngeal squamous cell cancers are reported annually in the United States. If a third is related to HPV infection, then potentially 10,000 cases could be annually prevented. With a 55% 5-year overall survival and an increased incidence noted in younger, nonsmokers and nondrinkers, a vaccine that could confer long-term immunity could have a huge impact (95).

Theoretically universal vaccination with the quadrivalent vaccine could lead to the elimination of the maternal and paternal reservoir of HPV and thus to a near eradication of RRP caused by HPV 6 and 11 (96). While moral objections to requiring HPV vaccinations are largely emotional, public health officials may have more justifiable concerns about the merits of HPV vaccination based upon the financial and logistic burdens that may be imposed on families and schools. Another legitimate concern is the adverse-event rates in mass scale programs. It is estimated that the cost to fully immunize all 11-year-old girls will exceed $850 million per year (97). Several cost–benefit analyses have shown the vaccine to be greatly cost-efficient, with 13 cents spent on vaccination resulting in the savings of $1 of health care (Fig. 94.5). This is anticipated to improve when the 9-valent HPV vaccine becomes commercially available, covering more of the HPV subtypes responsible for cervical and head and neck cancers. It has been estimated that herd immunity can be achieved if 80% or greater of girls are vaccinated (*JAMA* article). However, the currently recommended three dose regimen of the quadrivalent vaccine is only being given to about 27% of girls

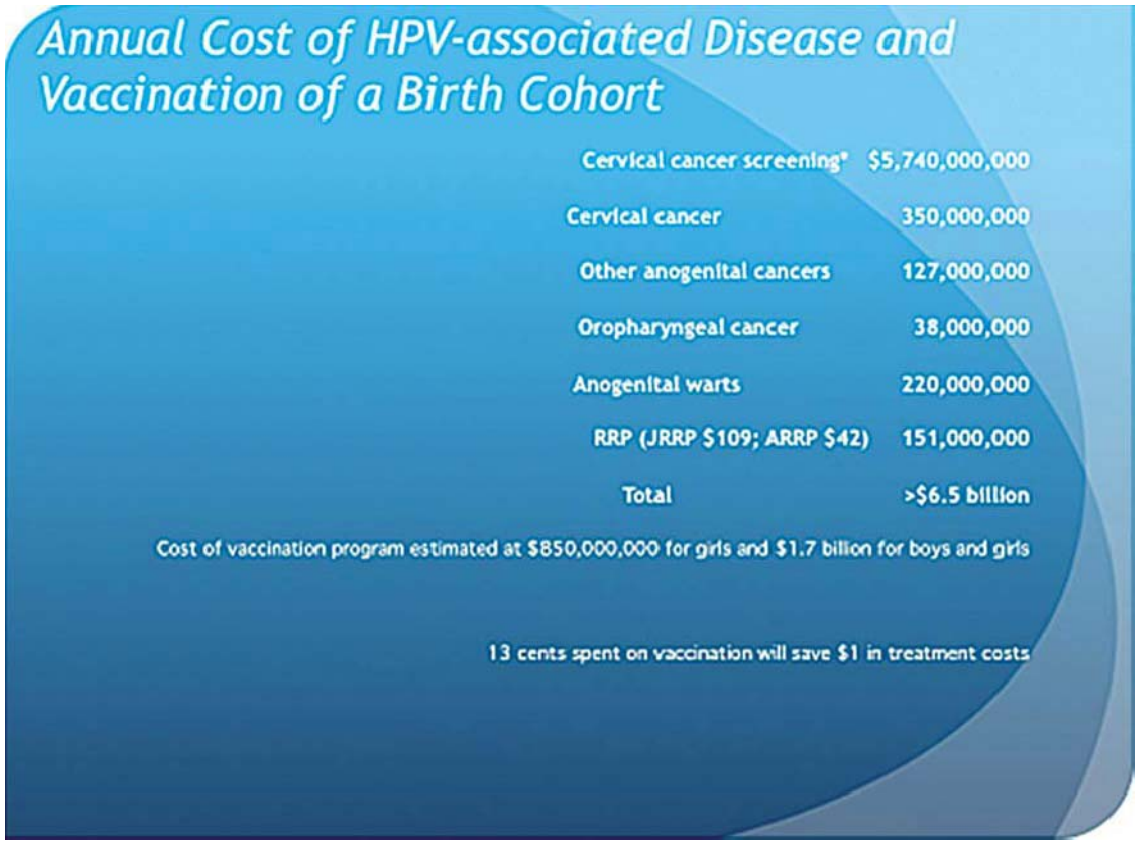

Figure 94.5 Cost of HPV preventative vaccination.

(44% are receiving at least one dose). With the added indication of the vaccine for prevention of anal cancer in boys, the FDA may consider in the near future changing its guidance from a permissive administration to a recommended vaccine. Given the rarity of RRP, multi-institutional studies will have to be continued for many years in order to observe any decrease in the incidence of RRP secondary to widespread vaccination.

It should be stressed that participation in national and regional protocols of adjuvant treatment modalities is essential for the scientific community to learn more about RRP. A national registry of patients with RRP has been formed through the cooperation of the ASPO and the CDC (8). The registry has tracked over 600 children at 22 sites with data on over 11,000 surgical procedures. It is hoped that the national registry will aid in the identification of patients suitable for enrollment in multi-institutional studies of adjuvant therapies and will help better define the risk factors for transmission of HPV and the cofactors that may determine the aggressiveness of RRP. Despite the progress that has been made in RRP research in the past decade, there are still numerous areas that require further investigation (Table 94.4).

A multicenter initiative organized through the RRP task force is currently ongoing to attempt to identify the host genes that govern susceptibility to RRP (98). It is hoped that by determining the host genes that govern susceptibility, we will enhance our understanding not only of RRP but also of host–viral interaction in general. Ultimately, this may lead to additional innovative treatment modalities.

TABLE 94.4 NEW HORIZONS UNDER INVESTIGATION FOR RRP

Role of interleukins, cytokines, and tumor necrosis factor
HPV preventative vaccination and the incidence of RRP
Multidrug chemotherapy for pulmonary cavitary disease
Role of cesarean section and gynecologic surgery during pregnancy in prevention of RRP
Effect of choice of surgical modality on RRP outcomes
Identification of host genes that govern susceptibility to RRP

RRP, recurrent respiratory papillomatosis; HPV, human papillomavirus

HIGHLIGHTS

- RRP is a frustrating, capricious disease with the potential for morbid consequences due to its involvement of the airway and the risk of malignant degeneration.
- No single modality of therapy has been consistently shown effective in eradicating RRP.
- The goals of surgical therapy are to maintain a safe airway with a serviceable voice while avoiding excessive scarring.
- Many adjuvant therapies have been investigated to supplement surgical therapy. Although several of these modalities have shown promise, no adjuvant therapy to date has cured RRP.
- Strides are being made in learning more about the natural history of the disease through the establishment of a registry of RRP patients at the CDC and in Canada and to help clinicians share information on and accurately follow their RRP patients over time.
- Future research is needed regarding prevention of transmission of HPV from mother to child. Specifically, the roles of cesarean section and gynecologic surgery during pregnancy need to be elucidated.
- Development of an HPV vaccine may ultimately prevent transmission of this disease eliminating it from the common practice of pediatric otolaryngologists in a similar fashion that acute epiglottitis has declined with the introduction of the HiB vaccine.
- Surgical therapy for RRP requires a skilled team consisting of otolaryngologists, anesthesia providers, and OR personnel working together in a facility properly equipped to manage difficult pediatric airways.
- Due to the recurrent nature of papilloma disease and the potential for airway obstruction, parental support and education can be invaluable to the safety of the child with RRP.

95 Adenotonsillar Disease in Children

Anita Jeyakumar *Sean Miller* *Ron B. Mitchell*

Adenotonsillar disease usually presents in children with either recurrent throat infections or sleep-disordered breathing (SDB). Twenty years ago, recurrent tonsillitis was the most common indication for tonsillectomy. Presently, the most common indication for tonsillectomy and adenoidectomy (T&A) is SDB. This shift comes as a result of an evolving understanding of the impact of SDB on childhood health and well-being and a renewed focus on ensuring evidence-based indications for surgical intervention.

Untreated SDB can negatively impact a child's quality of life, behavior, and school performance (1–3). Similarly, children with recurrent throat infections have more bodily pain and poorer general health and physical functioning compared to healthy children (4). In the appropriately selected child, T&A can eliminate or improve the morbidity of SDB and recurrent tonsillitis.

This chapter reviews the current knowledge of the clinical presentation and management of adenotonsillar disease in children.

EPIDEMIOLOGY

In 2006, the most recent data available, 530,000 tonsillectomies were performed in children younger than 15 years of age in the United States (5). The only procedure performed with greater frequency was myringotomy with tube insertion, estimated at about 667,000 in the same year (5).

In the early and midportion of the 20th century, T&A was the most common surgical procedure in the United States, with the indication primarily being recurrent throat infections (6). Secondary to a public backlash and scrutiny of tonsillectomy for unscrupulous indications and unproven efficacy in the late 1970s and early 1980s, there was a decline by about 50% to 75% in the number of T&A procedures performed. However, since then, the frequency of T&A has almost doubled, with the most common indication at present being SDB as opposed to recurrent throat infections (6–8). The incidence of SDB is known to peak during early childhood and to affect 1% to 4% of children (9). In addition, older children and young adults are more frequently being treated for SDB with T&A (10,11).

EMBRYOLOGY

Tonsils are lymphoid organs that develop from components of surface epithelium enveloped by mesenchymal stroma and subsequently populated by lymphocytes and immunologic mediators. Adenoids, also known as the pharyngeal tonsils, develop in close approximation to mucous glands along the posterior surface of the nasopharynx.

The basic structure of the adenoids is characterized by multiple shallow sagittal folds and plicae covered by respiratory epithelium. Invaginations and ingrowth of endoderm followed by programmed cell death creates the characteristic crypts of tonsillar tissue. Lymphoid follicles develop around these crypts and adjacent glandular ducts. Crypts begin to develop at 3 months of gestation and are fully developed by the seventh month. Immunoglobulin populations have been found present in embryonal adenoid tissue. The adenoids will often increase in size until the sixth to seventh year of life at which point they begin to diminish and subsequently atrophy by early puberty. The opening of the Eustachian tube is also variably lined by lymphoid tissue, the tubal tonsils (12).

The palatine tonsils derive from the endoderm of the ventral portion of the second pharyngeal pouch. This epithelium, in a similar manner to the adenoids, invaginates and branches within the surrounding mesenchyme and ultimately undergoes apoptosis to produce characteristic crypts. The capsule of the tonsil develops from a condensation of mesenchyme. Unlike the adenoids, the palatine tonsils are covered by squamous epithelium. Lymphocytes appear in the reticulum by the third month of gestation and become arranged as lymphatic nodules. Lymphocyte

proliferation and maturation then takes place within the surrounding mesenchyme. Definitive lymphoid organization around these crypts can be recognized by the final trimester of development (12).

The lingual tonsils develop along the posterior region of the base of tongue. This area is covered by mucous glands, which are subsequently infiltrated with lymphoid cells during the fifth month of development. Crypts of the lingual tonsils appear at birth and are more shallow and less complicated than their palatine counterparts (12).

Taken as a whole, the adenoids and tubal, palatine, and lingual tonsils form an anatomic arrangement, which is collectively known as Waldeyer ring (Fig. 95.1). The adenoids and tubal tonsils form the posterosuperior extent of the ring, the palatine tonsils provide the lateral portion, and the lingual tonsils at the base of the tongue provide the anteroinferior segment. The tissue of each portion has similar histologic appearance and function. Waldeyer ring serves as a component of the mucosa-associated lymphoid tissue for the upper aerodigestive tract. Table 95.1 summarized the distinctive properties of each component of Waldeyer ring.

The adenoid tissue lies at the superior aspect of the nasopharynx, extending laterally to the Eustachian tubes and the walls of the pharyngeal recess and lying in general approximation to the tubal tonsils, which may be present and surround the opening of the Eustachian tube. The blood supply of the adenoids is from the pharyngeal branch of the external carotid artery with some minor supply from the internal maxillary and facial arteries. Sensory innervation is provided by the glossopharyngeal and vagus nerves. The general shape of the adenoid tissue is that of a loosely defined pyramid with the adenoid apex pointed toward the nasal septum and base toward the posterior wall of the nasopharynx (12).

The palatine tonsils lie at the entrance to the oropharynx between the palatoglossus muscle, also known as the anterior pillar, and the palatopharyngeus muscle, or posterior pillar. The superior constrictor fascia serves as the lateral margin of the tonsillar fossa. The palatine tonsils are the only portion of Waldeyer ring with a discrete capsule and are the largest tonsils within the ring. The tonsillar capsule is a specialized portion of the pharyngobasilar fascia that covers the surface of the tonsil and extends into it to form septa that conduct the nerves and vessels. This capsule adheres to the surrounding fascia by loose connective tissue, forming a relatively avascular plane which is taken advantage of during tonsillectomy. During times of hypertrophy, the palatine tonsils may extend in a more caudal direction to become nearly confluent with the base of tongue and lingual tonsil tissue. Immediately lateral to the superior constrictor is the glossopharyngeal nerve, which may be injured during tonsillectomy. In cadaveric studies (13), the lingual branch of the nerve was shown to be just lateral and in about a quarter of cases adherent to the tonsillar capsule itself. Pain and dysgeusia are potential sequelae from injury to this nerve.

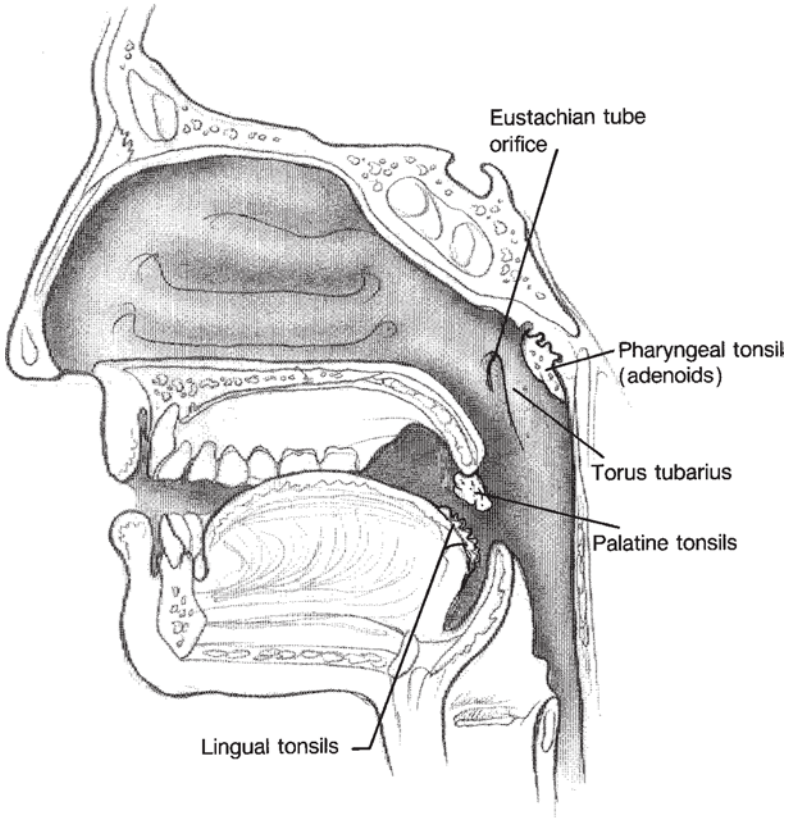

Figure 95.1 Lateral view of Waldeyer ring.

TABLE 95.1 COMPONENTS AND PROPERTIES OF WALDEYER RING

Type	Location	Capsule	Epithelium	Crypts
Adenoid	Superior aspect of nasopharynx	Incomplete	Predominantly: Ciliated pseudostratified columnar	Minimal
Tubal tonsil	Lateral aspect of nasopharynx, at Eustachian tube	None	Ciliated pseudostratified columnar	Minimal
Palatine tonsil	Lateral aspect of oropharynx between palatoglossus and palatopharyngeus	Incomplete	Nonkeratinized stratified squamous epithelium	Long, Branched
Lingual tonsil	Posterior to sulcus terminalis of the tongue	Incomplete	Nonkeratinized stratified squamous epithelium	Long, Unbranched

The blood supply to the palatine tonsils is variable, but in general, they are supplied by several branches of the external carotid artery: ascending pharyngeal, ascending palatine, and branches of the lingual and facial arteries. The blood supply enters from the lower portion of the palatine tonsil pole. The internal carotid artery (ICA) lies approximately 2 to 2.5 cm deep and posterolateral to the palatine tonsil; however, case reports (14) exist of aberrant ICA courses which come within 1 cm of the inferior pole. The ICA may have a tortuous and convoluted course of which the surgeon must be cognizant. Venous drainage is by way of a peritonsillar venous plexus, which surrounds the capsule and drains into the lingual and pharyngeal veins (12).

The lymphatic drainage of the tonsils is primarily to the superior deep cervical and jugular lymph nodes, which may become tender and inflamed during times of infection. The sensory innervation is from the glossopharyngeal nerve and some branches of the lesser palatine nerve via the sphenopalatine ganglion.

The histologic structure of the tonsils is closely related to its function as an immunologic organ. The epithelium of the crypt system acts as the immune system access route for inhaled and ingested antigens. These crypts are lined by a system of antigen-presenting cells that deliver the antigen to the immunologically active lymphoid cells in the tonsillar stroma.

IMMUNOPHYSIOLOGY

The tonsils and adenoids play an integral role in host defense, local immunity, and immune surveillance against invading antigens of the aerodigestive tract. Because the tonsils and adenoids do not have afferent lymphatic channels like other secondary lymph tissues, they are fed by surface epithelia. The aforementioned crypts serve to increase the surface area and effectively trap foreign material, both ingested and inhaled. These crypts are surrounded by numerous aggregates of cellular mediators of the immunologic system. Aggregates of B lymphocytes with more sparsely intervening zones of T lymphocytes and a diverse population of antigen presenting cells (macrophages, B cells, dendritic cells) are found in abundance within the subepithelial tissue of the tonsils (15).

These tissues survey the locally presented antigenic stimuli, destroy them, and generate effector and memory lymphocytes to be disseminated to other mucosal sites. They serve as an inductive site for local and distant antibody responses and generate immunologic memory independent of the systemic immune system. This function is most active during childhood and declines with age (16,17).

Microscopically, the adenoids have three types of surface epithelium: ciliated pseudostratified columnar, stratified squamous, and transitional epithelium. Chronically infected adenoids tend to have a predominance of squamous epithelium. One study demonstrated a significant transition trend to squamous metaplasia in chronically affected adenoid tissue (18).

Given the role in immunologic surveillance, some have questioned the impact of T&A on immunologic integrity. The results of several studies indicate that such interventions do not compromise the immune functions of children. The immunity of children after T&A has been shown to recover compared to their preoperative immune status, and to be similar to their age-matched healthy controls when the surgery is performed in young children and in late adolescence (19). Other studies have concluded that the effect of removal is essentially "clinically insignificant" and argue that no increase in the frequency of immunomodulated diseases is to be expected (20).

CLINICAL PRESENTATION

Adenotonsillar disease is characterized by either infections involving the lymphoid tissue, or hypertrophy or a combination of both. The disease processes can, and often will, affect the adenoids, tonsils, or both. Less often, adenotonsillar disease can be neoplastic. Table 95.2 provides a broad overview of adenotonsillar disease.

Infections

Viruses

Viruses play an important role as initiators of mucosal inflammation, crypt obstruction, and ulceration leading to bacterial superinfection. The clinical presentation of viral tonsillopharyngitis is similar to that of bacterial infection, but often with less severe symptoms, including sore throat, odynophagia, otalgia, headache, and fever. There is often tonsillar erythema and enlargement with or without exudates. The implicated viruses are the same as those involved in a variety of upper respiratory illness: rhinovirus, coronavirus, adenovirus, herpes simplex virus, parainfluenza virus, Epstein-Barr virus, and cytomegalovirus (21).

Of special note is herpangina caused by coxsackievirus. Often affecting young children, this disease may present as small vesicles with erythematous bases that eventually ulcerate and are typically present on the anterior tonsillar pillars, palate, and posterior pharyngeal wall.

Acute infections with Epstein-Barr virus may present as tonsillopharyngitis with dramatic tonsillar hypertrophy, sore throat, fever, cervical and diffuse lymphadenopathy, palatal petechiae, and malaise (21). The diagnosis is confirmed on the basis of clinical presentation, greater than 10% atypical lymphocytes on a peripheral blood smear, and a positive monospot (heterophile antibody) test (22). Care should be taken to not inadvertently prescribe amoxicillin or ampicillin as the risk of morbilliform rashes can approach 95% with this treatment (22).

TABLE 95.2 DIFFERENTIAL OF ADENOTONSILLAR DISEASE

Infection and/or inflammation
- Adenoids

Neoplasm
- Benign
- Lymphoproliferative
- Lymphoid hyperplasia
- Malignancy

Bacteriology/Microbiology

Any discussion of adenotonsillar infectious disease has to include several important observations. First, most infections can be linked to the presence of beta-lactamase producing organisms that distort the normal aerodigestive bacterial milieu and can cause commensal organisms to become pathogenic. Second, infections are often polymicrobial in nature and often include anaerobic pathogens. Third, obstruction of tonsillar crypts can serve as a nidus for bacterial stasis and can further perpetuate a condition of chronic infection, suppuration, and fistulae (23).

Studies of the bacteriology of adenoid tissue obtained from pathologic postoperative specimens demonstrate the presence of several aerobic species: alpha- and gamma-hemolytic streptococci, *Haemophilus influenzae*, *Staphylococcus aureus*, group A beta-hemolytic streptococci (GABA), and *Moraxella catarrhalis*. Anaerobic species noted include members of *Peptostreptococcus*, *Prevotella*, and *Fusobacterium*. Similar findings have been confirmed in tonsil isolates as well (24,25). Due to these findings and the previously mentioned premises, one must conclude that surface cultures have limited utility for identifying the causative organism, especially in chronic inflammation.

Generally, most authors attribute 15% to 30% of bacterial cases of acute tonsillopharyngitis to GABA, with a varying contribution from other pathogens, including group C beta-hemolytic streptococci, *Neisseria gonorrhoeae*, *Corynebacterium diphtheria*, *Chlamydia pneumoniae*, and *Mycoplasma pneumoniae* (21). Studies have shown that the presence of tonsillopharyngeal exudate and anterior cervical lymphadenitis increase the likelihood that the infectious agent is group A streptococcus (26).

The chronicity of adenotonsillar disease may be attributed to multiple overlapping infections caused by different pathogens within fistula and purulent pockets of the tonsil parenchyma even in the absence of clinical symptoms (23).

Hypertrophy

Although we distinguish between hypertrophy and infectious clinical presentations, it is true that most adenotonsillar hypertrophy is a result of low grade or chronic infectious disease of the involved tissues. Studies support a bacterial etiology for tonsillar hypertrophy (27). Some authors have argued for an etiologic role for *H. influenzae* in the pathogenesis of tonsillar hypertrophy in children (28). Adenoid hyperplasia has been demonstrated to be directly proportional to the number of lymphocytes and the bacterial load of the tissue (28). For the purposes of

this discussion, we will consider hypertrophy as a separate clinical entity, one which does not present with the signs and symptoms of acute or chronic infection—erythema, tenderness, lymphadenopathy, or fever. In practice, many children may have components of both infectious and hyperplastic morbidity.

Adenoid hypertrophy is a common cause of nasal obstruction in children. It can present as chronic or recurrent nasal discharge, snoring, SDB, recurrent otitis media, or Eustachian tube dysfunction (18). Physical examination often elicits a history of mouth breathing, hyponasal voice, and the classic "adenoid facies," characterized by an incompetent lip seal, a narrow upper dental arch, increased anterior face height, a steep mandibular plane angle, and a retrognathic mandible. This development occurs as the result in the changes in head and tongue position and muscular balance secondary to the open mouth breathing that accompanies nasopharyngeal obstruction (29). Recent studies confirm that there are changes in facial growth and development among children with adenoid hypertrophy. These changes are characterized by increased total and inferior anterior heights of the face, as well as more anterior and inferior position of the hyoid bone (30).

Tonsillar hypertrophy can present with dysphagia, SDB at night with gasping for breath, voice changes, and dental malocclusion. Children may even provide a subjective experience of having difficulty "getting food down" or the sensation of oropharyngeal fullness.

The presentation of new onset unilateral tonsillar hypertrophy is most likely due to infection, but the differential should include malignancy. Sudden enlargement of Waldeyer ring should raise suspicion for lymphoma, but actual use of asymmetric hypertrophy without concomitant symptomatology is often of poor predictive value (31). Unusual infections such as atypical mycobacteria, actinomycosis, and lymphoproliferative disease in solid organ transplant children need to be considered with asymmetric enlargement.

CLINICAL EVALUATION

Adenoids

Obstructive adenoid hyperplasia is diagnosed by clinical evaluation. Mouth breathing, snoring, and hyponasal speech are common presenting complaints. Rhinorrhea, postnasal drip, and chronic cough are common and nonspecific findings. The aforementioned adenoid facies may be present. Assessment of hyponasality is accomplished by having the child repeat words that emphasize nasal emission, which are phonemes using the "m," "n," or "ng" sound, such as milkman or mickey mouse and comparing them to words that do not, such as baseball or phrases such as "patty ate apple pie" (32).

Differentiating acute and chronic infections from sinonasal disease can be challenging. Often, acute and chronic adenoiditis can be confused and misdiagnosed as "sinusitis." Most children under the age of 6 will have effective resolution of these symptoms with adenoidectomy (33). Parents should be made aware that if symptoms persist after adenoidectomy, further investigation and treatment of sinonasal disease may be necessary to fully address the appropriate etiology.

A thorough physical exam includes at a minimum anterior rhinoscopy, which is easily facilitated in the cooperative child, with the use of an otoscope and large ear speculum. This allows the clinician to distinguish possible sources of nasal obstruction within the anterior nasal cavity, such as turbinate hypertrophy, edematous mucosa, or foreign body and to differentiate these from sources within the nasopharynx.

Palatal evaluation should also be undertaken, to ascertain the presence of submucous clefting, bifid uvula, or history of nasal regurgitation. This diminishes the possible complication of postoperative velopharyngeal insufficiency. Children with neuromuscular and central nervous system problems are also at increased risk for velopharyngeal insufficiency following adenoidectomy (32,34).

Evaluation of the adenoids in an uncooperative child can be difficult and can be accomplished using lateral neck radiographs, although these are often superfluous compliments to physical exam and history. More recently, an increasing number of children have been evaluated using office nasopharyngoscopy. This technique allows for direct visualization without radiation exposure. Nasopharyngoscopy offers an excellent view of the adenoids and adjacent structures. Parikh et al. (35) have proposed a grading system for endoscopic examination of adenoid hypertrophy that is validated and user-friendly. Other methods such as video fluoroscopy have been shown to be effective at assessing adenoid size but are less commonly used and carry unnecessary radiation exposure (36).

Tonsils

Physical examination should be performed with the child's mouth open and the tongue on the floor of the mouth, within the oral cavity. A tongue depressor should be used to depress the tongue with gentle and firm pressure along the oral tongue. Gagging and tongue extrusion will cause the tonsils to medialize and can produce the appearance of false enlargement. Having the child say "aah" will allow assessment of palatal integrity and motion. Tonsillar size may be measured on a scale of 1 to 4 with 1 (0% to 25% airway obstruction), 2 (25% to 50% airway obstruction), 3 (50% to 75% airway obstruction), and 4 (75% to 100% airway obstruction) (37). By convention, this grading scale is denoted as 1+ to 4+ (Fig. 95.2). Tonsillar hypertrophy is usually defined as falling within the 3+ to 4+ range.

The otolaryngologist must be cognizant of signs of chronic disease, such as peritonsillar erythema, tender

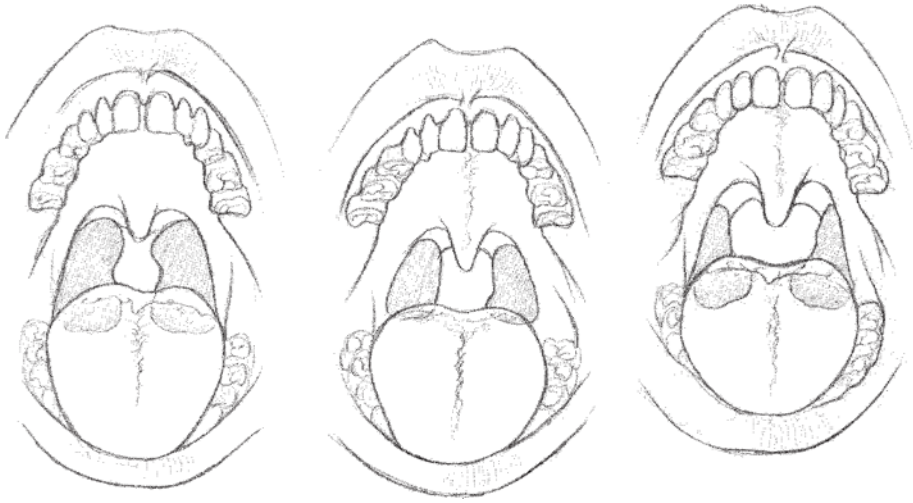

Figure 95. 2 Tonsil grading scale. (Adapted from Brodsky L, Poje C. Tonsillitis, tonsillectomy and adenoidectomy. In: Bailey BJ, ed. *Head and neck surgery-otolaryngology*, 4th ed., Vol. 84. Philadelphia, PA: Lippincott Williams & Wilkins, 2002:1185.).

cervical lymphadenopathy, tonsilloliths, smooth glistening tonsils, or excessively cryptic tonsils.

Of note, children at particular risk for the development of SDB secondary to tonsillar hypertrophy include those with craniofacial anomalies, Down syndrome, obesity, and neuromuscular or CNS abnormalities. These children may have symptoms not necessarily predicted by clinical presentation or tonsillar size.

MANAGEMENT

Infection/Inflammation

Management of a child with adenotonsillar disease depends on the underlying etiology and can include medical and surgical approaches. Acute infections need appropriate antibiotic therapy and symptom control. However, the majority of persistent adenotonsillar disease is considered a surgical problem.

Recurrent or chronic adenoiditis due to infection should be treated with an antimicrobial agent effective against beta-lactamase producing microorganisms. In terms of a durable response from other medical therapies, including inhaled nasal steroids for adenoidal hypertrophy, a Cochrane review (38) has shown only limited short-term benefit.

Acute tonsillitis should be managed with a rapid strep antigen screen and culture swab for definitive diagnosis. Rapid strep antigen screens have a reported sensitivity of 72% to 92%, specificity of 89% to 96%, and a positive predictive value of 68% to 89% (39). The most common bacterial pathogen in acute tonsillopharyngitis is GABA, with a recent meta-analysis attributing nearly 37% of all cases of acute pharyngitis to this pathogen (40). Fortunately, group A strep maintains almost universal sensitivity to penicillin. However, given the preponderance of beta-lactamase producing pathogens and their known influence in the development of tonsillar hypertrophy, the clinician may include a clavulanic acid scavenger as well to ensure appropriate antibiotic therapy and response.

Antibiotics have been demonstrated to offer modest benefits to the treatment of sore throat by shortening duration of symptoms by approximately 1 day (41). As previously discussed, a caveat to antibiotic therapy is the management of infectious mononucleosis. Children known to or suspected of having infectious mononucleosis should not be given amoxicillin or ampicillin containing antibiotics, in order to avoid the development of a rash.

When enlarged tonsils and adenoids cause an acute upper airway obstruction, a nasopharyngeal airway with intravenous steroids may be the most effective way to achieve immediate relief. When bacterial infection is suspected, antimicrobial therapy is initiated. Rarely is there an indication for immediate T&A in the acute setting.

Indications for tonsillectomy have been well discussed and examined throughout the otolaryngologic literature. Multiple studies and consensus statements from national panels have been undertaken to attempt to clarify an appropriate treatment algorithm for the clinician when addressing adenotonsillar disease and to advise appropriate interventions. In 2011, The American Academy of Otolaryngology–Head and Neck Surgery published a Clinical Practice Guidelines on the indications for tonsillectomy based on an extensive literature review and an expert panel that included both otolaryngologists and nonotolaryngologists. They made recommendations to address the two most common indications for tonsillectomy: recurrent tonsillitis and SDB (42), which are summarized at the end of the chapter.

In regards to recurrent tonsillitis, the recommendations endorse the more stringent Paradise criteria as a means for determining which children meet criteria to benefit from tonsillectomy (43). They endorse watchful waiting and close monitoring of episodes of tonsillitis for children who do not have a history of seven episodes in the past year or five episodes per year in the past 2 years or three episodes

TABLE 95.3 PARADISE CRITERIA FOR TONSILLECTOMY (43)

Criteria	Definition
Minimum frequency of sore throats	Seven or more episodes in the preceding year, OR Five or more episodes in each of the preceding 2 years, OR Three or more episodes in each of the preceding 3 years
Clinical features (sore throat plus the presence of one or more qualifiers)	Temperature > 38.3°C, OR Cervical lymphadenopathy (tender or size > 2 cm), OR Tonsillar exudate, OR Positive culture for group A β-hemolytic streptococcus
Treatement	Antibiotics administered in Conventional Doses
Documentation	Each episode and qualifying features noted in a clinical record, OR *If not fully documented*, subsequent observation of two episodes of throat infection and frequency and clinical features consistent with initial history (observation usually recommended for 12-month period)

per year in the past 3 years. This recommendation is made on a thorough examination of the available literature and while weighing the risk and benefits of intervention against watchful waiting. This is based on studies that show that a high proportion of children may experience resolution of symptoms without tonsillectomy (44).

The Paradise paper and subsequent studies demonstrate that the most benefit is achieved in children who are significantly and not just moderately affected by tonsillitis (Table 95.3) (43). A Cochrane review also notes a modest improvement in sore throat for less severely affected children (41). However, even those meeting the criteria should be advised of the modest anticipated benefits of tonsillectomy weighted against the natural history of resolution and the risk of surgical morbidity and complications. The panel suggested that there was not a clear preponderance of benefit over harm for tonsillectomy for the indication of tonsillitis.

In addition, the recommendations further delineate the conditions that should be met to be considered a discrete episode of tonsillitis and not merely pharyngitis or upper respiratory tract infection. The criteria include temperature greater than 38.3°C, cervical adenopathy, tonsillar exudates, or a positive test for GABA.

The recommendations do allow for other compelling indications for tonsillectomy for infectious etiology, including modifying factors such as antibiotic allergy or intolerance, PFAPA (periodic fever, aphthous stomatitis, pharyngitis, and cervical adenitis), or history of peritonsillar abscess (PTA). Histories of rheumatic heart disease or glomerulonephritis are additional compelling indications.

The decisions to pursue tonsillectomy for previously described indications including halitosis, chronic tonsillitis, malocclusion, cryptic tonsils, chronic GABA carriage, tonsillitis, and illness, which is impacting school attendance or performance, have not been vetted with sufficient rigor to be recommended as necessitating or benefiting from tonsillectomy based on the present literature. The panel allows for child and clinician discussion and evaluation of these relative indications. They recommend that intervention or watchful waiting be made on a case-by-case basis.

Sleep Disorders/Breathing

In contrast to these weaker indications, what has demonstrated clear benefit and health improvement is the use of tonsillectomy in the management of SDB and its associated morbidity.

SDB is characterized by recurrent partial or complete upper airway obstruction during sleep, resulting in disruption of normal ventilation and sleep patterns (45). Snoring neither indicates nor excludes SDB, but is known to affect many children. SDB is multifactorial disease, which develops in the presence of a combination of anatomy, neuromuscular tone, and adenotonsillar hypertrophy. Therefore, children with special considerations may have SDB in the absence of adenotonsillar hypertrophy. Additionally, it is known that tonsil size does not correlate to SDB (46).

Hypertrophy of the adenoids, tonsils, or both can obstruct the upper airway and result in SDB, alveolar hypoventilation and cor pulmonale, and these conditions respond well to T&A (47). In addition, SDB is known to increase the risk for hyperactivity and symptoms of attention deficit hyperactivity disorder (ADHD) (48,49). Children with SDB may have enuresis (50), behavior problems, poor school performance, reduced quality of life, and growth problems. It is important to note that the severity of SDB does not correlate with the severity of behavioral or quality of life scores.

Although polysomnography is the "gold standard" for diagnosing SDB in children, it is unnecessary in every child. For healthy children with the common presentation

of SDB: somnolence, behavioral problems, poor cognitive performance, nocturnal enuresis, and a physical exam consistent with adenotonsillar hypertrophy, with or without witnessed apneas, it is reasonable to proceed with T&A without prior polysomnogram. There is a 25% to 75% success rate in predicting obstructive sleep apnea clinically, and this number is not improved with the use of questionnaires or nocturnal home video recordings (51). In most instances, preoperative polysomnography is only necessary when the child has medical comorbidities that make them a poor candidate for elective tonsillectomy, age less than 3 years, absence of adenotonsillar hypertrophy, or physical exam findings that are not consistent with airway obstruction (52).

SDB may persist or recur after tonsillectomy and may require other interventions, including the use of continuous positive airway pressure. Parents must be made aware of the limitations and possible outcomes prior to surgical intervention.

In cases of unilateral tonsillar hyperplasia, chronic bacterial infection or infection with atypical pathogens such as actinomycoses or fungi is implicated. Often, asymmetry is explained by asymmetric location within the tonsillar fossa. Tonsillar asymmetry in isolation is not an indication for tonsillectomy (53). Tonsillar asymmetry in the absence of other associated symptoms of malignancy may be most appropriately managed by a period of watchful waiting (31). If there is clinical suspicion of lymphoma, the surgeon should consult preoperatively with pathologist or oncologist to determine the appropriate medium in which to transmit the surgical specimen.

Careful medical history should be taken with specific reference to any bleeding history in the child or family or the use of medication that may lead to increased bleeding. Studies have shown that routine use of coagulation studies is of little utility and is of little prognostic significance for predicting posttonsillectomy hemorrhage, even in children with history of mild bleeding episodes (54). Some authors have advocated for the use of coagulation studies for children presenting with posttonsillectomy hemorrhage in order to identify occult coagulopathy, although a cost–benefit analysis has not been performed (55).

SURGICAL TECHNIQUES

Tonsillectomy

The earliest description of tonsillectomy is credited to Cornelius Celsus, a Roman encyclopedist, around 30 AD. The procedure has been practiced and improved upon tirelessly throughout the intervening millennia. Surgical techniques have evolved considerably to include instruments such as knives, fingers, guillotines, wires, and strings. However, despite the evolution of the techniques and its near ubiquitous use as a medical therapy, physicians have been unable to eliminate the incumbent morbidity and mortality of this common procedure. Over the last two decades, in order to reduce some of the morbidity and expedite recovery time, clinicians have expressed renewed interest and research in different surgical approaches and technology for tonsillectomy.

The complete removal of the tonsil and its capsule had its origin in the early 20th century in the United States (56). Complete removal of the tonsil, however, leaves the musculature of the pharynx exposed to heal by secondary intention, which is thought to be the source of much of the morbidity of the procedure. This aspect of this common surgical procedure, namely healing, by secondary intention is unique and not routinely practiced in nearly any other surgical location within the body.

Since 1980, electrocautery has become the instrument of choice for tonsillectomy due to its familiarity to surgeons, ease of use, and limited intraoperative blood loss. According to the latest survey of members of the American Academy of Otolaryngology and the American Society of Pediatric Otolaryngology, electrocautery is the preferred method for tonsillectomy by 55% of otolaryngologists, coblation tonsillectomy by 20% to 25%, cold steel techniques by 10%, and other techniques including microdebrider partial tonsillotomy in about 10% (57). Other techniques include the use of laser, microscopic bipolar cautery, temperature radiofrequency reduction, and ultrasonic scalpel.

Recently, there has been increasing interest in performing a partial tonsillectomy, or tonsillotomy, to maintain the tonsillar capsule and reduce postoperative pain and bleeding. Most of the literature on tonsillotomy has been published from European centers (58). Large case series have shown that tonsillar regrowth occurs in about 0.5% to 6% of children with a smaller percentage requiring completion tonsillectomy. The operation takes several minutes longer than electrocautery tonsillectomy and the intraoperative blood loss is marginally greater. The role of intracapsular techniques for managing children with recurrent tonsillitis is still unproven (43,59,60).

All methods include an identification of tonsil boundaries, preservation of normal anatomic architecture, and observance of meticulous hemostasis. The surgeon must be aware at all times of the possibility of cautery injury, which can lead to devastating burns of the oral commissure, skin, or ignition of inhalational anesthetics.

Adenoidectomy

Adenoidectomy techniques in the past have employed the use of adenoid curettes or adenotomes with hemostasis achieved with packing; topical hemostatic agents like bismuth, tannic acid, Neosynephrine, or oxymetazoline; or the use of suction electrocautery. Concerns and complications with these techniques centered on excessive bleeding, difficulty in teaching the technique to inexperienced surgeons, and the almost certainty of residual tissue around

the Eustachian tube and posterior choana. Suction Bovie cautery, microdebrider, and coblation are currently widely used for removal of adenoids and have been shown to be effective, efficient, and associated with better hemostasis (61). A known disadvantage of these techniques is the increased expense as compared to traditional methods.

OUTCOMES

Infections

With the exception of management of PTA, the benefit of tonsillectomy for infections continues to be contentious. Most clinical trials about this topic are biased because of poorly defined criteria, nonrandom child selection, exclusion of severely affected children, and reliance on caregivers for data collection. Two studies by van Staaij et al. (62) and Burton and Glasziou (44) suggested a statistically significant reduction in the frequency of infections in severely affected children, but a less substantial benefit in mildly affected children. Paradise et al. had strict inclusion criteria (Table 95.3), and showed that children randomized to two groups had little difference in sore throat symptoms after 3 years of follow-up (43). In fact, in a follow-up study by Paradise et al. (63) where they used less stringent criteria for tonsillectomy, they noted that there was no difference in sore throats for moderate to severe disease after 12 months of follow-up. Data from several studies were pooled in a Cochrane review that showed that children undergoing tonsillectomy experience 1.4 fewer episodes of sore throat in the first year versus the control group (after eliminating the postoperative throat pain) (44). In cases of moderate to severe preoperative sore throats, surgery was associated with 0.2 fewer episodes of sore throats in the postoperative period.

Approximately 30% of children with a PTA satisfy criteria for a tonsillectomy and approximately 10% will subsequently develop a second abscess. To avoid the associated morbidity, expense, and possible deep neck space infectious complications, a tonsillectomy is indicated for children experiencing their second PTA. The tonsillectomy is usually performed as a routine procedure after the PTA has resolved (64).

Sleep-Disordered Breathing

Pediatric SDB is associated with behavioral problems that include hyperactivity, aggression, anxiety, depression, and somatization (1). Mitchell and Kelly (1) reported a significant improvement after T&A for SDB in a high proportion of children with externalizing and internalizing behavioral problems. The improvement was dramatic; was maintained for up to 18 months after surgery; and was seen regardless of gender, age, ethnicity, parental education, or parental income. The degree and severity of behavioral problems in children with SDB as well as improvements after T&A were similar regardless of the severity of the sleep disorder (1).

Health care costs are higher in children with SDB. Tarasiuk et al. (21) compared health care costs in children with SDB who had a T&A to children with untreated SDB and to healthy controls. Children with SDB demonstrated a significantly higher rate of antibiotic use, more hospital visits, and an overall 215% elevation in health care usage. They reported that total health care costs were reduced by one-third in children with SDB following T&A (as opposed to the control or untreated group). The reduction in health care costs was a result of a reduction in outpatient and emergency room visits, hospitalizations, and pharmacy costs.

In a recent meta-analysis, Friedman corroborated a successful outcome for children with polysomnographic documentation of SDB with improvement in polysomnography scores for 66% of children and cure, defined as an apnea–hypopnea index of less than 1, in 60% of children (65). Obese and overweight children do not incur as significant improvement in their SDB as their normal-weight counterparts. Further management strategies may be indicated for successful treatment (66).

Quality of Life

Studies have demonstrated that SDB imparts a quality of life burden, which is similar to children afflicted by juvenile rheumatoid arthritis (47). Dramatic improvements in quality of life scores after T&A for SDB have been shown in a number of studies (1,67,68) and meta-analysis review (47). The improvements were seen both within 6 and 18 months after surgery. The dramatic improvements in quality of life occurred regardless of the severity of SDB. In a similar manner to findings in outcomes in SDB severity, obese children experience less dramatic improvement in quality of life following T&A as compared to nonobese counterparts (68).

Studies of quality of life show an improvement in children who undergo T&A for recurrent tonsillitis. However, studies to date have had significant limitations. Only two studies exclusively enrolled children (69,70), but neither study clearly defined recurrent tonsillitis, both lacked control groups and had low response rates with poor follow-up. Both studies were also limited by poor postoperative data collection. There is a definite need for clearly defined quality of life studies for infectious pathologies and tonsillectomy.

CONTRAINDICATIONS

Contraindications to T&A include coagulation abnormalities that should be addressed prior to surgery, and often require a multidisciplinary approach including hematology involvement and coordination (71). A child with a cleft palate and other craniofacial abnormalities may be predisposed to velopharyngeal insufficiency. These children will rarely undergo complete adenoidectomy. Children with

acute illnesses that might impair the ability to maintain adequate postoperative hydration or safely undergo general anesthesia should defer elective surgery.

COMPLICATIONS

Although lightly considered by the general public and many within the medical profession, tonsillectomy is a major surgical procedure that has the potential for hospitalization, anesthesia risks, prolonged postoperative pain, and ongoing health care costs. The most common major complication after surgery is postoperative hemorrhage. Hemorrhage can be primary (within 24 hours of surgery) or secondary (more than 24 hours after surgery). The incidence of primary hemorrhage ranges from 0.2% to 2.2%, while the incidence of secondary hemorrhage ranges from 0.1% to 3% (72). The management of postoperative hemorrhage may include another operation to control the bleeding or readmission for observation.

In a recent review of a large population (17,000) experiencing posttonsillectomy hemorrhage in Wales, risk factors identified included child age greater than 12, male sex, and surgical techniques (73). The risk for secondary hemorrhage was greater for techniques involving heat, with coblation experiencing a nearly 13-fold increased risk. This finding was in accord with other large studies, which demonstrated the superiority of cold technique in reducing secondary hemorrhage (74). A previous review of nearly 16,000 children in Germany, including both children and adults, identified male sex, infectious mononucleosis, and a history of recurrent tonsillitis as risk factors for hemorrhage (72).

Other complications of T&A include postoperative dehydration secondary to pain, nausea, vomiting, otalgia, postoperative pulmonary edema, nasopharyngeal stenosis, velopharyngeal insufficiency, and intraoperative complications (trauma to teeth, larynx, pharynx, soft palate, laryngospasm, aspiration, endotracheal tube fire, cardiac arrest, lip burn, eye injury, mandible dislocation, or fracture). Clearly, complications are more common in children with other comorbidities such as craniofacial disorders, heart disease, bleeding disorders, and children younger than 3 years (75–77). It is estimated about 1.3% of children have a delayed discharge from the hospital immediately postoperatively, and up to 3.9% children have a secondary complication requiring readmission.

Airway complications are a major cause of medical malpractice after tonsillectomy (78). A recent study identified children with respiratory complications following T&A. Complications ranged from oxygen desaturation requiring supplementation to pulmonary edema. The study found that predictors of postoperative complication could be surmised from preoperative polysomnography and included apnea–hypopnea index, hypopnea index, body mass index, and oxygen saturation nadir (79). Although most children will not have this data available, the clinician is wise to be aware of potential adverse predictors and to tailor postoperative care, including admission for observation in high-risk children, accordingly. In addition, children experiencing recalcitrant postoperative emesis, children with craniofacial syndromes, those who live a great distance from the hospital and those with other serious medical comorbidities, such as diabetes mellitus, seizure disorders, and sickle cell disease, are better served by postoperative admission for observation.

Rare complications of surgery have been reported, including vascular injury, subcutaneous emphysema, jugular vein thrombosis, atlantoaxial subluxation, taste disorders, persistent neck pain, and death. Grisel syndrome is a rare complication following operative procedures or infections in the upper aerodigestive tract. The hypothesized pathogenesis is due to the higher flexibility of the ligaments during inflammation, which leads to increased laxity and subluxation between the axis and atlas of the cervical spine and skull base. When the inflammation heals, the child may experience neck fixation in a rotated position (80).

Mortality has been estimated to be 1 in 16,000 to 1 in 35,000, although these numbers were produced during the 1970s and there is an absence of more recent estimates (80). About one-third of mortality were related to bleeding. In many cases, mortality was associated with other medical comorbidities or impediments to proper health care access (81,82). Another review of posttonsillectomy hemorrhage noted that repeated episodes of hemorrhage could portend a higher risk for mortality (83).

Adenoidectomy has its own attendant risks. Postoperative hemorrhages, velopharyngeal insufficiency, persistent Eustachian tube dysfunction from iatrogenic manipulation, nasopharyngeal stenosis, c-spine subluxation from hyperextension during surgery are all known risks for children undergoing adenoidectomy. Special attention must be given to children with Down syndrome because of the risk of atlantoaxial subluxation. The most common complaint in children undergoing adenoidectomy is persistent postoperative malodorous breath, which may persist for up to 2 weeks. Although postoperative hemorrhage is not as common in children undergoing adenoidectomy alone, other rates of complications are encountered with frequency similar to that of tonsillectomy.

PERITONSILLAR ABSCESS

PTA is the most common deep space infection of the neck. It may be due to contiguous spread from the tonsil parenchyma or as secondary to infection of the minor salivary gland (Weber gland) located at the superior pole of the tonsil. The abscess itself will form in the potential space between the tonsil capsule and the muscles of the superior constrictor, the lateral extent of the tonsillar fossa. In some cases, the infection may violate this fascia and lead to a parapharyngeal abscess by direct extension.

Exact incidence has been estimated at 30 per 100,000 people per year. It occurs more often in children older than 12 years of age, but it has been reported at any age. The incidence of PTAs is coincident with that of streptococcal tonsillopharyngitis—early winter and spring. The classic presentation is that of a prolonged sore throat, which may sometimes improve but then remits. The child will present with the so-called hot potato muffled voice, fever, trismus, malaise, and dysphagia. Tender cervical lymphadenopathy and otalgia may also be present. Physical exam will reveal medial and inferior displacement of the involved tonsil, effacement of the tonsil, and uvular deviation away from the involved tonsil. The diagnosis is clinical. Some authors have advocated the use of intraoral ultrasound to aid in diagnosis, but most rely on physical exam alone. CT scan is the best choice for diagnosing suspected PTA in young uncooperative children (84). Children younger than 5 years who present with poor oral intake, high fever, drooling, and trismus should be suspected of having a PTA (85).

Treatment is incision and drainage. Some authors advocate that needle aspiration is the best initial treatment, with incision and drainage performed if needle aspiration fails (86). In a cooperative child of appropriate age, the procedure can be done at the bedside with a topical anesthetic. Even in a noncooperative child, studies have shown that intravenous sedation provided by emergency room staff may eliminate the need for surgical drainage in the operative room (87). In one series, children of ages 4 to 18 years were treated successfully in this manner without untold complication or adverse effects (88). If the child is able to tolerate Oral intake following the procedure, he or she may be discharged. Treatment should also include the use of intravenous hydration, and appropriate analgesia as well as antibiotic coverage for staphylococcal organisms.

Conversely, if available staffing for conscious sedation is not available or the decision is made to proceed with general anesthetic, immediate tonsillectomy appears to be a safe and effective surgical technique for the management of PTA and parapharyngeal abscess. One study demonstrated that it markedly reduced hospital stay (when performed early in the course of the disease) and duration of antibiotic therapy (89). Another study concluded that so-called quinsy tonsillectomy may be the treatment of choice for any child undergoing general anesthesia for treatment (84).

CONTROVERSIES

There continues to be controversy concerning the superior technique for tonsillectomy, one which minimizes hemorrhage, cost, and operative time. Randomized controlled trials and large prospective cohort studies demonstrated a higher risk of postoperative hemorrhage after hot tonsillectomy compared with cold dissection (90–92). In a systematic review of hot (monopolar electrosurgery) versus cold knife tonsillectomy, only 6 of 815 prospective trials met the necessary inclusion criteria and revealed that postoperative hemorrhage rates were not significantly different when comparing the two methods (93). A Cochrane review showed no significant difference in coblation versus electrocautery (73,94).

Antibiotics are commonly used in the routine, perioperative care of children undergoing tonsillectomy, despite convincing evidence of no beneficial impact on recovery (except for possibly reduced fever). In a review of this practice, there was no demonstrable impact on pain, return to normal activity, or the need for use of analgesics. The authors also note the adverse consequences of known increase in bacterial resistance with the use of antibiotics and risk of allergic reactions (95). The cessation of routine perioperative antibiotic use is recommended.

Nonsteroidal anti-inflammatory drugs (NSAIDs) are used infrequently for pain control based on unfounded concerns about increased postoperative hemorrhage, which are not supported by systematic reviews of randomized trials (96). A meta-analysis demonstrated an increased risk of posttonsillectomy hemorrhage with the use of aspirin after tonsillectomy but not for nonaspirin NSAIDs such as diclofenac and ibuprofen (97). Conversely, codeine is often used after tonsillectomy despite no benefit over acetaminophen in randomized controlled trials plus a known adverse event profile that includes nausea and vomiting, and genetic polymorphisms in codeine metabolism may eliminate any analgesic efficacy (98).

In a related consideration, a review of local anesthetic use in both adults and children undergoing tonsillectomy, either infiltrated submucosally or topically, pre- or postexcision offered no improvement in postoperative pain (99).

For several decades, evidence has accumulated that the administration of a single intraoperative dose of dexamethasone in children undergoing tonsillectomy results in decreased postoperative nausea and vomiting, a major source of morbidity (100). Although initial studies demonstrated an increased risk of hemorrhage (100), subsequent reviews have countered that finding (101). In addition, a Cochrane review demonstrated a more rapid advancement to full diet for children receiving dexamethasone (102). Therefore, when considering the balance of the literature, the most recent clinical practice guidelines endorsed the use of intravenous dexamethasone for children undergoing T&A.

CLINICAL PRACTICE GUIDELINES

In 2010, Clinical Practice Guidelines were published for tonsillectomy in children aged 1 to 18 without complicating comorbidities (including diabetes, cardiopulmonary disease, craniofacial disorders, congenital head and neck abnormalities, coagulopathies, or hemoglobinopathies). The intent was to guide clinicians into selecting children who would benefit from tonsillectomy and to optimize their perioperative care. Tables 95.4 and 95.5 are excerpts from the guidelines document summarizing some of the pertinent comments (102).

TABLE 95.4 SUMMARY STATEMENTS OF THE 2010 CLINICAL PRACTICE GUIDELINES (42)

Statement	Summary
1	Watchful waiting for recurrent throat infections if: • <7 episodes in the last year OR • <5 episodes in the last 2 years OR • <3 episodes in the last 3 years
2	Tonsillectomy for infections recommended for the following: • ≥7 episodes in the last year OR ≥ 5 episodes in the last 2 years OR ≥ 3 episodes in the last 3 years • WITH medical documentation of each sore throat, AND one or more of the following: ◦ Temperature >38.3°C ◦ Cervical Adenopathy ◦ Tonsillar Exudate ◦ Positive test for Group A β-hemolytic streptococcus
3	Tonsillectomy may be considered for the following children who do not meet criteria according to statement 2—children with: • Multiple antibiotics intolerance/allergy • PFAPA • History of PTA
4	In consideration for tonsillectomy for sleep disordered breathing, caregivers should be asked about comorbidities such as growth retardation, poor school performance, enuresis, and behavioral problems
5	In children with abnormal polysomnography and hypertrophic tonsils, tonsillectomy can provide a means to improve the health in the children
6	Sleep disordered breathing may persist after an T&A, requiring further management (see Table 95.5)
7	A single dose on intraoperative intravenous dexamethasone during tonsillectomy can significantly reduce postoperative nausea and vomiting
8	Children undergoing tonsillectomy do not need perioperative antibiotics
9	The clinician needs to advocate for pain management, and educate the guardians about the importance of assessing and managing pain
10	Clinicians should evaluate their rates of primary and secondary postoperative hemorrhage annually

TABLE 95.5 2010 CLINICAL PRACTICE GUIDELINES (42)

Tonsillectomy and sleep disordered breathing: counseling

1	Hypertrophic Tonsils may contribute to SDB in children
2	SDB is often multifactorial
3	Obesity plays a key role in SDB in some children
4	Polysomnography is considered the gold standard for the diagnosis of SDB. It is not necessary in all cases, and access may be limited by availability of a sleep laboratory or willingness of third party payers to cover the cost
5	Tonsillectomy is effective in the treatment of SDB in 60%–70% children with tonsillar hypertrophy
6	Tonsillectomy is effective in ONLY 10%–25% of obese children with SDB
7	Caregivers need to be counseled that tonsillectomy is not curative in all cases of SDB especially in children with obesity

NEOPLASIA

As stated in Table 95.2, neoplasia, while uncommon in children, is certainly a consideration in adults. In children, sudden rapid growth of adenotonsillar tissue, with persistent adenopathy should merit consideration of lymphoma. In adults, the tonsil is frequently a site for squamous cell carcinoma. Unusual presentation of adenotonsillar disease should get further evaluation, often with a biopsy and multidisciplinary work up. Further discussion is beyond the scope of this chapter.

CONCLUSIONS

Adenotonsillar disease and its management has enjoyed a long and, at times, contentious existence within the medical field and within otolaryngology. In the properly selected child, T&A can decrease the incidence of infection, correct or improve SDB and its sequelae, and improve quality of life. Although questions remain and controversies persist, this chapter provides a foundation and framework for approaching this critically important topic.

HIGHLIGHTS

- Adenotonsillar disease usually presents in children with either recurrent throat infections or SDB. Presently, the most common indication for T&A is SDB.
- The blood supply to the palatine tonsils is from branches of the external carotid artery: ascending pharyngeal, ascending palatine, and branches of the lingual and facial arteries.
- Approximately 30% of bacterial cases of acute tonsillopharyngitis are caused by GABA, with a varying contribution from other pathogens, including group C beta-hemolytic streptococci, *N. gonorrhoeae, C. diphtheria, C. pneumoniae,* and *M. pneumoniae.*
- Acute tonsillitis should be managed with a rapid strep antigen screen and culture swab for definitive diagnosis. Fortunately, group A strep maintains almost universal sensitivity to penicillin which is the first line treatment.
- Although polysomnography is the "gold standard" for diagnosing SDB in children, it is unnecessary in every child. For healthy children with the common presentation of SDB it is reasonable to proceed with T&A without prior PSG.
- The American Academy of Otolaryngology–Head and Neck Surgery published a Clinical Practice Guidelines on the indications for tonsillectomy based on an extensive literature review and an expert panel that included both otolaryngologists and nonotolaryngologists. They made recommendations to address the two most common indications for tonsillectomy: recurrent tonsillitis and SDB.
- Although lightly considered by the general public and many within the medical profession, tonsillectomy is a major surgical procedure that has the potential for hospitalization, anesthesia risks, prolonged postoperative pain, and ongoing health care costs. In the properly selected child, T&A can decrease the incidence of infection, correct or improve SDB and its sequelae, and improve quality of life.

Congenital Anomalies of the Nose

96

John P. Bent *David E. Conrad*

Midline congenital nasal lesions are rare, occurring in one out of every 20,000 to 40,000 births (1). Whenever an infant presents with a midline nasal mass, the diagnostic considerations include nasal dermoid, glioma, and encephalocele. These congenital and relatively uncommon lesions share aberrant skull base development, namely, errors in formation of the anterior neuropore. Consequently, the nasal mass often maintains a central nervous system (CNS) connection. As a result, workup must proceed judiciously but promptly, because both reckless and delayed intervention carries risks.

Radiologic advances have tremendously facilitated the management of congenital nasal anomalies. Magnetic resonance imaging (MRI) and/or computed tomography (CT) allows detailed evaluation of the pathology and any associated defects at the skull base. As a result, surgical planning, including the potential role, if any, for the neurosurgeon can be carefully scripted. A variety of approaches gives the surgeon added flexibility, and despite the sensitive location of these defects, most affected children carry an excellent prognosis.

EMBRYOLOGY

To understand the intricacies of congenital midline nasal masses, one must comprehend the normal development of the anterior neuropore (primitive frontonasal region). The two important steps of this process are the formation of the neural tube from ectoderm and the subsequent migration of neural crest cells into mesenchyme to form the skull base and face (Fig. 96.1).

A midline neural groove appears along the dorsal surface of the embryo by the third week of gestation. Shortly thereafter, the ectodermal plate thickens, ultimately forming a neural tube. This precursor to the CNS fuses during the fourth week, with closure beginning in the midportion of the embryo before progressing both anteriorly and posteriorly. Neuropores at the caudal and cranial ends of the neurotube close last. The anterior neuropore, composed of a midline funnel-shaped dural diverticulum, forms at the optic recess of the sphenoid sinus, while the area immediately proximal to the anterior neuropore forms the frontal, nasal, and ethmoid structures.

As neural tube closure progresses, neural crest cells in the lateral portions of the neural tube migrate between the tube and the surface ectoderm into the mesenchyme that will eventually form bone and cartilage. The anterior neuropore is the most distal point of neural crest cell migration; the lack of neural crest cells and the relatively late tube closure predispose this region to developmental defects.

Once neural crest cells migrate into position, underlying mesenchyma organizes into skeletal structures, forming several important spaces (Fig. 96.2):

- Fonticulus nasofrontalis—the fontanelle between the inferior frontal and nasal bones
- Nasal capsule—the precursor to the nasal cartilages and septum, which is continuous with the ethmoid labyrinth
- Prenasal space—between the nasal bones and nasal capsule
- Foramen cecum—the region between the ethmoid and frontal bones, which connects with the prenasal space and the location where the cribriform plate condenses

Under normal conditions, these spaces involute during fetal growth.

Whether congenital anomalies of the nose are related to genetic or environmental factors, or both, remains unknown. Laboratory research suggests that extracellular proteins guide the adhesive and migration properties of the neural crest cells (1). Failure of normal neural crest cell embryology may lead to one of the following congenital lesions.

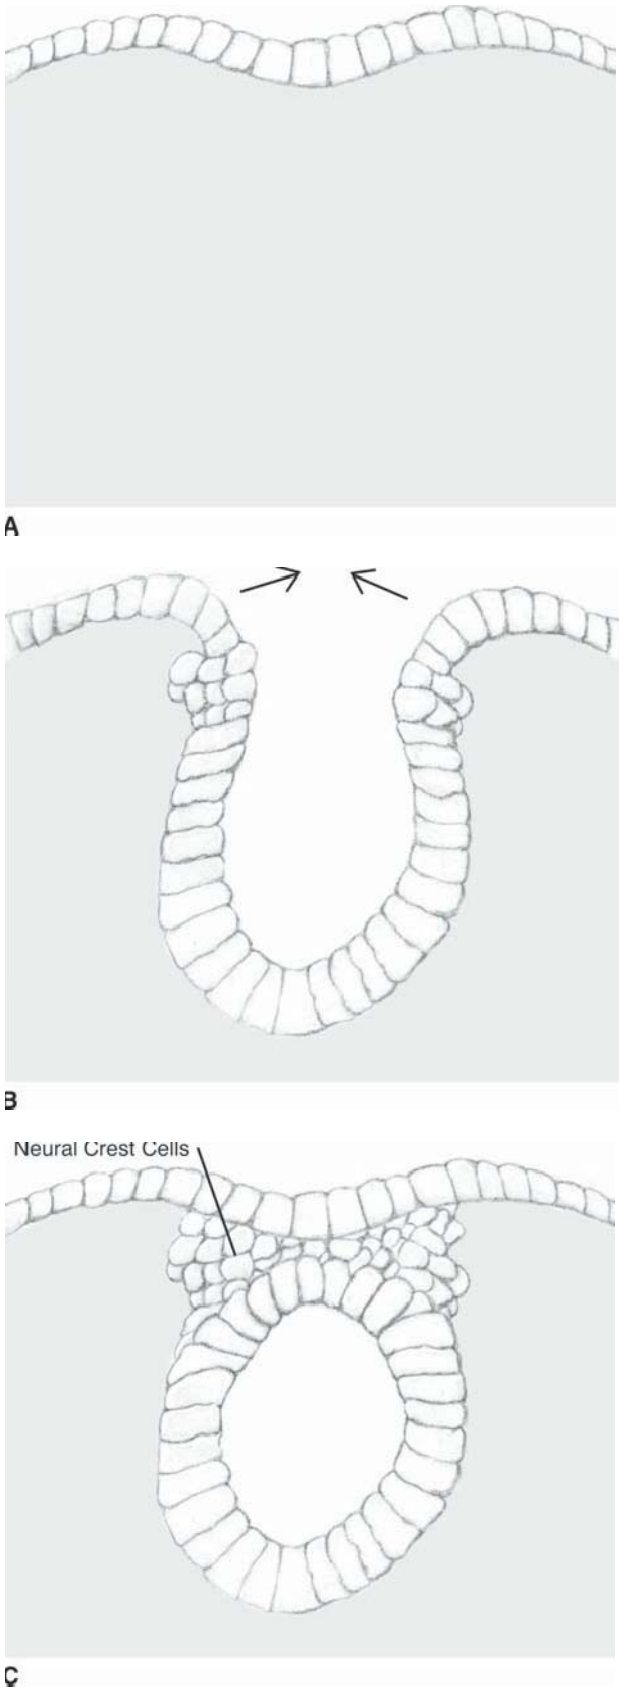

Figure 96.1 Neural tube formation. Dorsal view of embryo with developing neural groove. Note closure in midline first. **A:** Neural groove. **B:** Deepening groove. **C:** Neural tube separated from surface ectoderm; neural crest cells interspersed between surface and neural tube.

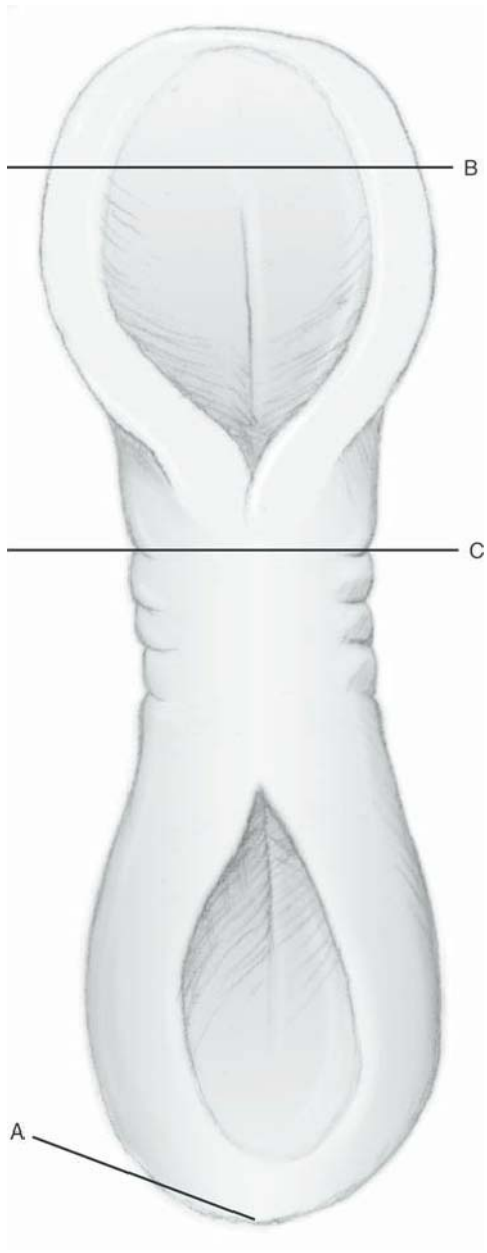

Figure 96.1 (*Continued*) A. Posterior neuropore, B. Anterior neuropore, C. Surface ectoderm covering neural groove.

Dermoid

Surface ectoderm and neuroectoderm lie in direct contact before mesenchymal infiltration, particularly at the junction of bone plates. If developing skin adheres to fibrous tissues of the nasal capsule in the prenasal space or fonticulus, it may be drawn posteriorly and superiorly, forming a squamous epithelial lined tract toward the anterior skull base. Animal models suggest that the failure of separation between neuroectoderm and surface ectoderm may involve insufficient apoptotic cell death during the ventrodorsal patterning of the neural tube (2). Aberrant dural attachments could allow a tract connecting skin to the dura via the foramen cecum, surrounded by condensing bone

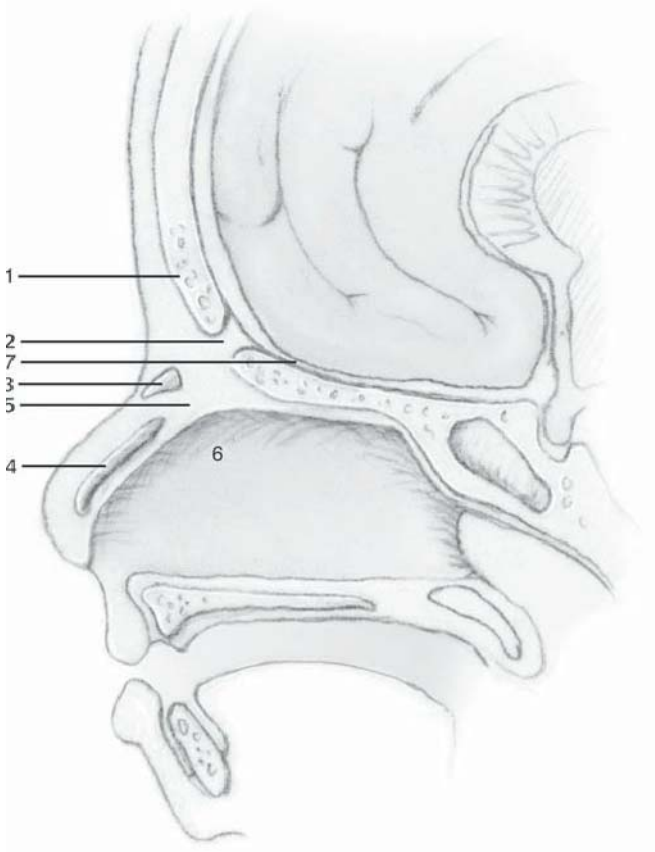

Figure 96.2 Normal embryonic anatomy of nose and anterior skull base. *1*, frontal cartilage; *2*, fonticulus nasofrontalis; *3*, nasal bone; *4*, nasal cartilage; *5*, prenasal space; *6*, nasal capsule; *7*, dura.

(Fig. 96.3). Once the tract forms, dermoid cysts may appear anywhere along the pathway. Alternative simplistic theories have suggested that dura becomes entrapped in the fetal septum, or pockets of epithelium become entrapped below the fusing ectoderm (3).

Glioma

Several theories also exist as to glioma embryogenesis. According to Gorenstein et al. (4), gliomas most likely form when cranial suture closure isolates brain tissue from the intracranial cavity. The fibrous stalk some gliomas maintain to the CNS supports this theory and suggests a developmental relationship between gliomas and encephaloceles. Less prominent theories of glioma formation include a nidus of ectopic neuroepithelia or an outgrowth of olfactory tissue through the cribriform plate (1).

Encephalocele

Like gliomas, encephaloceles probably originate from faulty closure of the skull; unlike gliomas, with encephaloceles the bone never closes, leaving a persistent intracranial–extracranial defect. As with dermoids and gliomas, the precise cause of this dysmorphism remains elusive. Speculation holds that anywhere along the line of neural tube closure, there may be a barrier or delay in neural crest cell migration. Subsequently, mesenchyme forms improperly, leaving the skull base open and allowing herniation of neural tissue (5). Because the midline is the furthest point of migration, this region naturally comprises the site of such defects. Figure 96.4 depicts the parallel between glioma and encephalocele formation.

CLINICAL AND PATHOLOGIC FEATURES

Dermoids contain both mesodermal and ectodermal components and, consequently, may have hair follicles, sweat gland, smooth muscle, and sebaceous tissue, in addition to their squamous epithelial lining. Nasal dermoid cysts represent approximately 8% to 10% of head and neck dermoids and 1% of all dermoids (6). Most dermoids have a sinus tract exiting via a minute skin opening along the nasal midline (Fig. 96.5). This feature distinguishes it from epidermal inclusion cysts, which also lack mesodermal components. The tract usually contains one, but occasionally

there are multiple cysts along its pathway. It may manifest cutaneously anywhere from the glabella to the columella but most typically exits over the dorsum at the osteocartilaginous junction. Craniofacial abnormalities, such as craniosynostosis, cleft lip and palate, and hemifacial microsomia, may also be present (7). Presenting symptoms may include a localized mass lesion over the nasal dorsum, erythema and tenderness, sebaceous or purulent discharge, or simply parental anxiety about cosmesis. Approximately 50% of patients will have a widened nasal dorsum and hypertelorism (8). The sinus tract may be short and the cyst small, but it may extend to the intracranial cavity through the foramen cecum. Cases with an intracranial connection pose an increased risk of meningitis.

Gliomas usually present early in life with symptoms of nasal obstruction. They have a 6:3:1 ratio of extranasal:intranasal:combined lesions (4). The masses are usually not midline, associated with a sinus tract, compressible, expandable with crying, or transilluminating. These qualities help distinguish gliomas from dermoid cysts and encephaloceles. Approximately 15% maintain a connection with dura; this phenomenon applies more to intranasal than extranasal gliomas (9). Such connections will occur through either the foramen cecum or the nasofrontal suture and place affected children at risk for developing meningitis.

Figure 96.5 Sinus tract opening on nasal dorsum.

Encephaloceles contain both meningeal and brain tissue. They tend to be more medially based than gliomas. For purposes of this discussion, meningoceles, which contain meningeal but not glial tissue, are also referred to as encephaloceles. Unlike gliomas, encephaloceles always occur through a significant skull base defect, and as a result, they carry a graver prognosis. Furthermore, these patients are more likely to have associated syndromic features or comorbidities such as Beckwith-Wiedemann syndrome (10). Encephaloceles are classified as occipital, basal, or sincipital, based on the location of the skull base defect. Occipital encephaloceles represent 75% of these defects but are not covered herein due to their lack of proximity to the nose.

Sincipital encephaloceles, also known as frontoethmoidal encephaloceles, comprise 15% of encephaloceles. They occur between the frontal and ethmoid bones at the foramen cecum, immediately anterior to the cribriform plate. Sincipital encephaloceles may be further subdivided as follows (Fig. 96.6):

1. Nasofrontal—These defects are located at the glabella between the nasal and frontal bones (Fig. 96.7). Commonly, these patients have lateral displacement of the medial orbital walls and inferior displacement of the nose.
2. Nasoethmoidal—The sac exits through the foramen cecum, passing under the nasal bones and above the upper lateral cartilages, creating a lateral nasal mass. Consequently, the upper lateral cartilages and septum are distorted and displaced inferiorly.
3. Nasoorbital—Like the nasoethmoidal encephalocele, the nasoorbital encephalocele transverses the foramen cecum before extending into the orbit via a defect in its medial wall.

These lesions are usually pulsatile and classically show expansion with crying, straining, or jugular vein compression (Furstenberg sign).

Basal encephaloceles generally manifest no craniofacial disfigurement, except occasional widening of the nasal root or hypertelorism. They are less common than

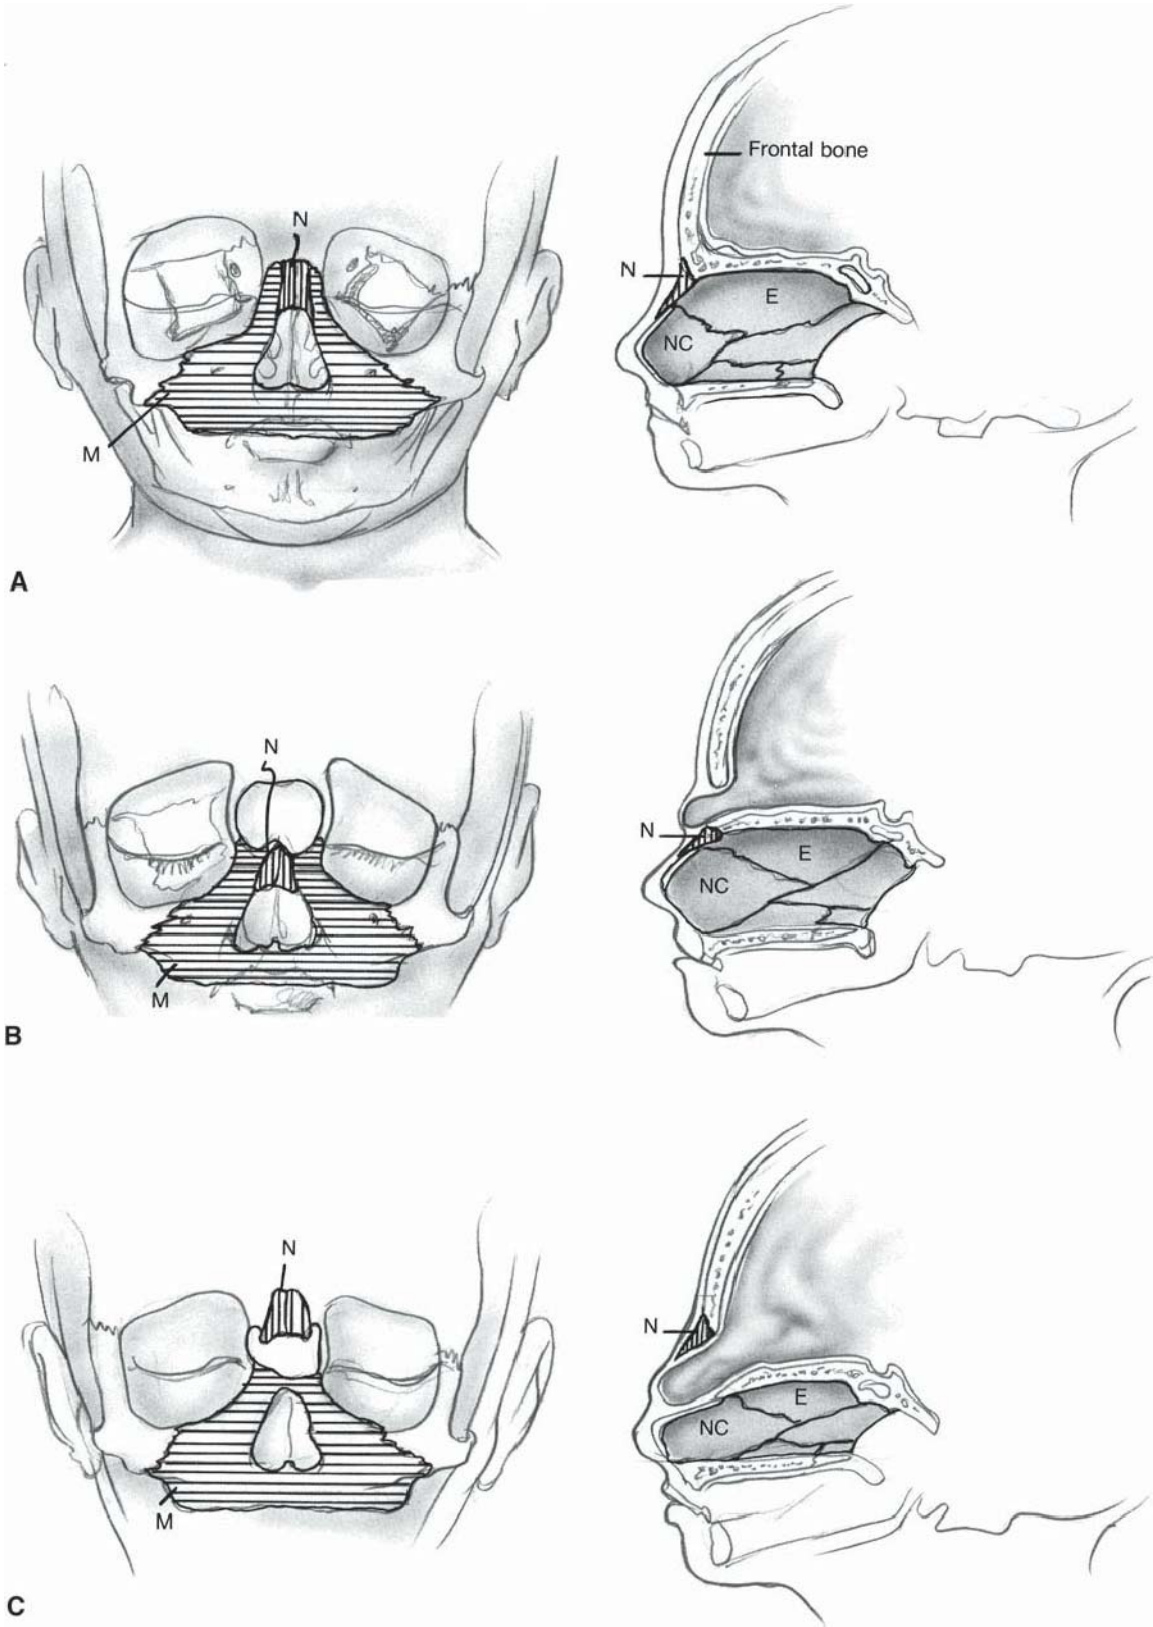

Figure 96.6 Sincipital encephaloceles. E, ethmoid bone; M, maxilla; N, nasal bones; NC, nasal cartilage. **A:** Normal. **B:** Nasofrontal encephalocele, with bony defect superior to nasal bones. **C:** Nasoethmoidal encephalocele, with bony defect inferior to nasal bones.

Figure 96.7 Sagittal MRI of nasofrontal encephalocele.

sincipital or occipital encephaloceles; four subtypes have been described (11):

1. Transethmoidal—The most common variant extends medial to the superior turbinate via a cribriform plate defect.
2. Sphenoethmoidal—The sac protrudes into the nasopharynx via a defect between the posterior ethmoid and the anterior sphenoid wall.
3. Transsphenoidal—The sac also presents in the nasopharynx, exiting intracranially through an open craniopharyngeal canal.
4. Sphenomaxillary—This encephalocele crosses the orbit via the superior and then inferior, orbital fissure to reach the sphenomaxillary fossa.

Basal encephaloceles cause nasal obstruction. Typically, intranasal encephaloceles can be differentiated from polyps via their location medial, not lateral, to the turbinates. Since these lesions may not present with any external facial abnormalities (namely Sphenoethmoidal, Transsphenoidal subtypes), the Otololaryngologist must perform a thorough intranasal exam to differentiate more benign causes of nasal obstruction from a congenital anomaly.

Typical features of nasal dermoids as well as gliomas and encephaloceles are depicted in Table 96.1.

EVALUATION

The differential diagnosis for a congenital midline lesion of the nose includes epidermoid cyst, hemangioma, teratoma, neurofibroma, lipoma, and lymphangioma. In some instances, midline nasal lesions can be detected on routine prenatal sonography (12). Therefore, the physician must supplement physical examination findings with a pointed radiographic workup to assess the anatomic pathway of the lesion. In some cases, pathways that appear to connect a mass to the intracranial cavity on MRI or CT may only represent a fibrous stalk that does not pose a risk to the patient. In instances in which a child presents with an external midline mass without a sinus tract, differential diagnosis includes glioma and encephalocele. Cephaloceles classically enlarge with crying and with jugular compression (positive Furstenberg sign). Because of the small but real possibility of meningitis from an intracranial connection, or the less threatening but still legitimate complication of gradual bony destruction and nasal deformity, a radiologic workup must also be initiated for lesions without a sinus tract. In an infant, these imaging studies can usually be obtained during routine sleep; preschool children older than 6 months usually require sedation. Despite the likely need for patient sedation, the otolaryngologist should promptly obtain an imaging study, because the risk from delayed treatment of an intracranial defect outweighs any concerns regarding anesthesia in the radiology suite.

MRI is the favored imaging modality for suspected anterior neuropore anomalies (7,8,13). For the infrequent circumstance of an anticipated large skull base defect, as with encephaloceles, three-dimensional CT has proven benefit (14). In general, CT tends to give better bone detail, whereas MRI best illustrates soft tissue. The presence of a bifid crista galli and enlarged foramen cecum is highly suggestive of intracranial involvement and implores the need for neurosurgical consultation (13). Although CT best displays the crista and anterior skull base, MRI can adequately image these structures. MRI also has the advantage of providing direct sagittal images, as well as a clear outline of the lesion in contrast to surrounding tissue (Fig. 96.8). Furthermore, MRI poses no risk of radiation. Huisman et al. (15) reported two patients with MRIs showing possible intracranial components that were not detected by CT or surgery. Therefore, MRI should be supplemented with a CT as needed for detailing the anterior skull base or nasal bones, or for clarifying ambiguous intracranial irregularities. Imaging should include the nasal tip to the anterior cranial fossa, including the entire nasal ethmoid and orbital regions.

SURGICAL TREATMENT

Controversy exists regarding both the timing and method of surgery. By delaying intervention, the physician risks growth of the lesion and infection. In 1951, Matson and Ingraham (16) showed that patients treated after an intracranial complication fared worse than those treated prophylactically. For this reason, lesions with confirmed intracranial connections should be treated without delay. On the other hand, if MRI clearly demonstrates no intracranial connection, delays of 2 to 5 years may be contemplated prior to surgery, as long as no infection develops within the cyst. Postponing surgery allows the child time for growth, facilitating the surgical

TABLE 96.1 CLINICAL FEATURES OF CONGENITAL NASAL MASSES

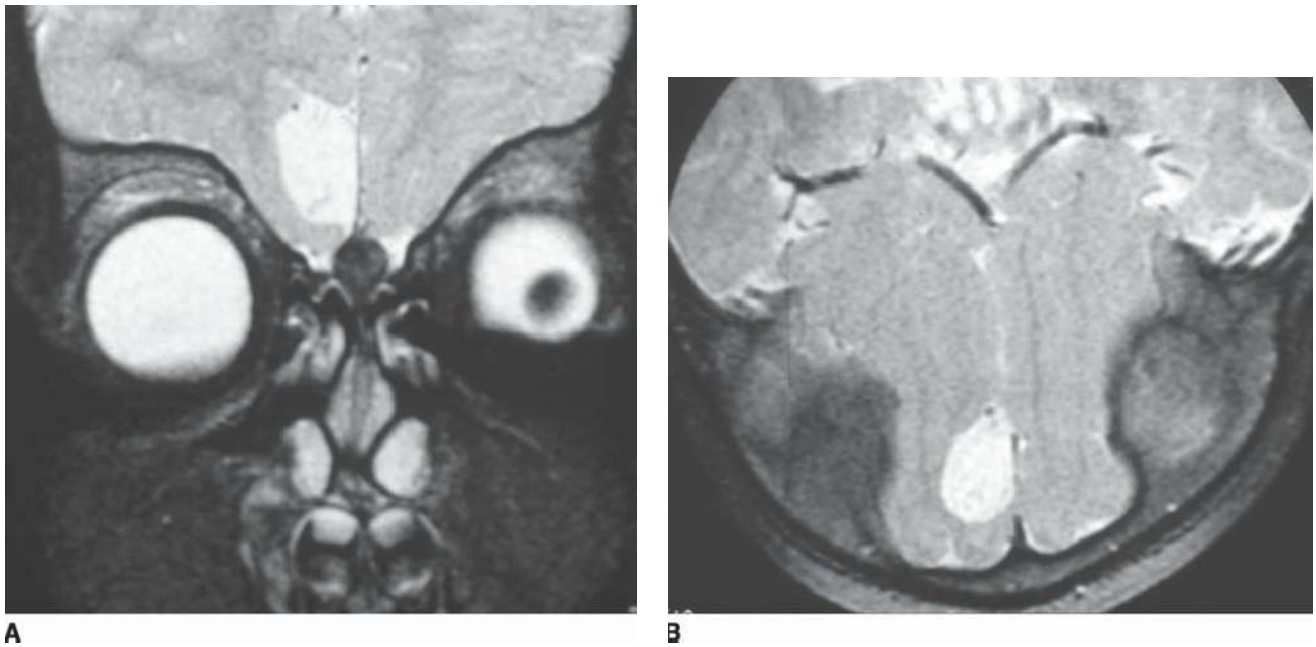
Encephalocele	S	S	S	N	Y

Y, yes; N, no; S, sometimes; U, usually; R, rarely.

dissection and diminishing the risks of altered nasal growth from tissue disruption. The physician must consider these benefits as well as the family's concerns before making recommendations about surgical timing.

Authorities favor a variety of surgical approaches for nasal dermoid cysts, including vertical or horizontal midline incision, lateral rhinotomy, transglabellar incision, or an external rhinoplasty approach. Those placed over or parallel to the nasal dorsum have been the mainstay of surgical exposure over the years (Fig. 96.9), and resulting scars are usually very subtle. However, alternatives that minimize scarring over the dermis must be considered, particularly in this era of enlightened, "minimally invasive" surgery. Pollock (17) suggested a transverse rhinotomy or a vertical zigzag rhinotomy to minimize wound contracture. Mankarious and Smith (18) described the external rhinoplasty incision, using a dermoid punch to release the skin pit from adjacent dermis. Because the dermal sinus tract tends to penetrate the nasal bones inferiorly, the open rhinoplasty provides excellent exposure (Fig. 96.10). Combining this with a vertical midline osteotomy, as necessary, to separate the nasal bones, provides virtually unimpeded exposure to the anterior skull base. Although the midface degloving approach prides excellent exposure to the midface and eliminates the need for a transcolumellar incision, it does not allow for the degree of midline, cephalad exposure afforded by the open rhinoplasty approach. The open rhinoplasty also allows simple reconstruction of the nasal dorsum, as needed, to minimize resulting dorsal depression. It must be noted, however, that an external incision over the nasal dorsum is always required to free the tract from its exterior attachment to nasal dorsal skin regardless of adequate exposure achieved through an external rhinoplasty approach. Parents should be educated appropriately on the inevitability of an exterior scar over the nasal dorsum. In the infrequent case of a dermoid sinus tract located superiorly over the glabella, an external rhinoplasty approach would be insufficient, and the patient would probably be best served with a transglabellar approach (19).

Regardless of the incision made, once the surgeon has followed the sinus tract through the nasal bones, magnification and otologic instruments greatly facilitate the



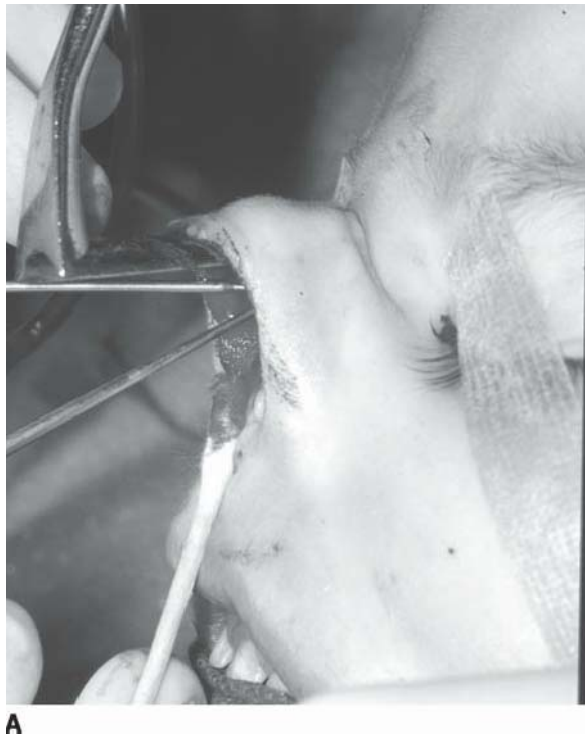


Figure 96.8 **A,B:** Coronal and axial MRI showing frontal lobe dermoid cyst.

procedure. The cyst wall should be kept intact and carefully dissected free of the adjacent bone and soft cavity within which it is contained. A neurosurgeon should be consulted in advance to be available for unexpected intracranial communication. On approaching the skull base, the lesion should come free or terminate in a fibrous stalk. If there is any question about the stalk representing an epithelial lined tract penetrating the skull base, a frozen section may be taken of its most superior, extracranial extent. Many authors advocate the residual tract can be ligated (20). One author advocates full removal of the tract due to the scattering of adnexal structures throughout the tract, which may contribute to recurrence (20). Histologic evidence of an epithelial lined tract would require a craniotomy to complete the excision. Without histologic or radiographic proof of intracranial extension, a craniotomy should *not* be commenced. Recurrence ranges from 6% to 12% and can generally be managed in a straightforward fashion (1,21).

Figure 96.9 Vertical midline incision.

A

B

Figure 96.10 **A:** Open rhinoplasty incision with retractor in place, demonstrating wide exposure. **B:** Specimen removed easily via open rhinoplasty.

Gliomas may be excised intranasally. Ideally, the surgeon can identify the stalk and amputate it so that no gross tissue remains *in situ*. Depending on the lesion's location, an external skin incision may be required. Rahbar et al. (1) recently reported a series of 10 gliomas excised without complication or recurrence. Naturally, a neurosurgeon should be available to help with unexpected skull base defects.

Lesions with a potential or known intracranial component must be managed jointly by otolaryngology and neurosurgery. Generally, the otolaryngologist will initiate a midface approach, after which the neurosurgeon will gain intracranial access via a separate, sterile field, using a bicoronal flap and frontal craniotomy. After delivering the specimen, the neurosurgeon typically repairs the skull base defect with a periosteal flap, and then the otolaryngologist returns to close midface incisions with cosmetic techniques. In the case of encephaloceles, the entire procedure may be performed by the neurosurgeon, with the otolaryngologist available to provide intranasal exposure as needed.

Because encephaloceles have the broadest skull base defects of the three congenital abnormalities discussed in this chapter, they have the highest potential for complications. Cerebrospinal fluid (CSF) leaks pose the most common problem. Although encephaloceles fall within the purview of neurosurgeons, otolaryngologists may play a supportive role in closing the defects via endoscopic exposure from below or in helping manage and repair postoperative CSF rhinorrhea. The addition of fibrin glue and an array of absorbable nasal packing increase the rhinologist's armamentarium for these functions.

HIGHLIGHTS

- Nasal dermoids, gliomas, and encephaloceles share embryogenesis but usually can be differentiated based on clinical features.
- Potential or actual CNS communications pose the most challenging aspect of managing these three lesions.
- Once a congenital nasal mass is suspected, MRI should be obtained. CT should be used if MRI leaves any doubts as to bone anatomy or intracranial extent.
- Approximately 25% of dermoids and 15% of gliomas have intracranial extension, which carries the risk of meningitis and therefore warrants prompt surgical treatment. Surgery for lesions without proven intracranial extension may be deferred temporarily.
- Well-planned surgical treatment with neurosurgical consultation usually leads to successful outcomes. Encephaloceles carry the worst prognosis because of the size of the associated skull base defects and associated morbidities.

ACKNOWLEDGEMENTS

We would like to acknowledge Dr. Roy Sessions (22) for his invaluable leadership and pioneer work describing nasal dermal sinuses.

Pediatric Rhinosinusitis

97

Rodney P. Lusk

The goal of this chapter is to review the etiology, diagnosis, and medical and surgical management of acute and chronic pediatric sinusitis. The diseases associated with rhinosinusitis (or sinusitis) are varied and difficult to differentiate (Table 97.1). It is now recognized that prolonged purulent rhinorrhea is not the norm. Children have an immature immune system and, if they attend day care, have an increased exposure to upper respiratory tract infections and possible recurrent sinusitis. Not infrequently, parents are asked to remove their children from the day care center if purulent rhinorrhea is present. This in turn can result in absenteeism from work and lost revenue for the employee and the employer. Sinuses are present in even the youngest children and can be infected. Chronic sinusitis usually involves both the maxillary and the anterior ethmoid sinuses with almost equal frequency.

SIGNS AND SYMPTOMS

Differentiating recurrent acute and chronic sinusitis is difficult because of a lack of specificity of the signs and symptoms. In addition the symptoms are frequently suppressed with antibiotic therapy, further confusing the diagnosis. Upper respiratory tract infections are frequently confused with sinusitis, and the primary delineation between the two appears to be the chronicity of the infection. Wald (1) noted that symptoms of the common cold improve in 5 to 7 days, and if the symptoms persist longer than 10 days, the symptoms are likely to be secondary to either an acute sinusitis or to persistent symptoms of chronic sinusitis. Acute sinusitis will take as long as 3 weeks to resolve symptoms. Historical documentation becomes confusing when antibiotics are prescribed as they suppress symptoms. Dr. Wald called the two types of sinusitis: persistent and severe, which occur secondary to an upper respiratory tract infection, and more severe infections, which are associated with a temperature of above 103°F rectally and thick, purulent nasal discharge. She argues that most nonsevere sinus infections resolve spontaneously, whereas more severe sinusitis requires treatment with antibiotics (1). Signs and symptoms and their severity may vary with the patient's age (Table 97.2). The young patient often has nasal congestion and anterior purulent rhinorrhea. The older patient may not be as symptomatic but complains of nasal congestion, postnasal drip, or sore throat secondary to the chronic drainage. Cough is a frequent complaint and is usually more severe at night. Daytime cough is more significant, however, as it is more likely to be associated with sinusitis. The relation between cough and chronic sinusitis is not clear. The symptom of chronic cough is most dramatic in the asthmatic patient, whose asthma attacks are frequently exacerbated by acute infections. Fever is much more common in the younger patient and is a frequent complaint, although rarely documented in the office.

Pain may manifest itself in a variety of ways. Younger children are irritable and may manifest head banging. The older patient complains of headaches and may be able to localize the area of pain. Unrelenting pain isolated over the vertex or back of the head without other symptoms may be associated with sphenoid sinusitis and needs to be ruled out with a CT scan (2,3). A significant problem with symptom assessment in chronic sinusitis is inadequate documentation. Two good validated instruments, SN5 (4) and S5 (5), are available but not frequently used.

PHYSICAL EXAMINATION

Signs of sinus infections include nasal congestion with dilatation of the mucosa, giving it a bluish appearance. Nasal discharge is often present with a variety of viscosities and may be clear, yellowish, or greenish; the clear drainage is generally thought to be associated with allergies, whereas yellow or greenish drainage is thought to be associated with a viral or bacterial infection. Another common but

TABLE 97.1 DIFFERENTIAL DIAGNOSIS OF DISEASES COMPATIBLE WITH PEDIATRIC CHRONIC SINUSITIS

Chronic sinusitis
Adenoid hypertrophy
Recurrent upper respiratory (viral) infections
Allergies
Immune deficiencies
Ciliary dyskinesia

TABLE 97.3 DIAGNOSIS PHYSICAL EXAMINATION IN CHRONIC SINUSITIS

1. Only anterior rhinoscopy can be performed in most children.
2. Visualize the septum then middle turbinate and then the middle meatus laterally.
3. A clear middle meatus does not ensure that no sinus disease is present.
4. Look for purulent discharge at the middle meatus.
5. Polyps are unusual in children. Think of cystic fibrosis, fungal sinusitis, and NARES syndrome.

nonspecific sign is dark inferior eyelids with puffiness over the maxilla. The physical examination of the child is difficult primarily because of poor compliance (Table 97.3). The approach to the child must be slow and nonthreatening. Head movements from side to side and the narrowing of the nasal vestibule brought on by crying make the examination virtually impossible. If the child refuses examination, little can be gained by trying to force the examination. The tools used to examine the nasal vault may include a nasal speculum and head mirror, microscope and nasal speculum, otoscope, flexible nasal pharyngoscope, or rigid telescope. The Viroscope, by Welch Allyn, offers a unique method of performing anterior nasal examinations. The light headlight is quite bright, and the anterior nasal airway can be viewed through lenses that narrow the parallax of the observer. This allows good visualization of the anterior nasal airway and middle meatus. Regardless of the method used, anterior rhinoscopy is all that can be accomplished, except for nasal pharyngoscopy, which can be performed with the flexible nasopharyngoscope. The flexible scope is most advantageous in the older postoperative patient.

It is best to examine the ears first with an otoscope. If the child tolerates otoscopy, the physician has gained the child's confidence, and anterior rhinoscopy can then be attempted with the otoscope. If all goes well, then vasoconstriction can be best accomplished with 0.05% oxymetazoline. A mixture of 1:1 0.05% oxymetazoline and 4% lidocaine will effectively anesthetize and vasoconstrict the nose for nasopharyngoscopy. After several minutes, the nose is reexamined to evaluate for possible purulence that has flowed into the anterior nasal vault. In children, polyps usually signal cystic fibrosis or allergic fungal sinusitis. It is encouraging if the middle meatus is clear and without edema, but this does not assure a disease-free sinus. Examination with a rigid telescope can be performed in the unusually cooperative child with local anesthesia. Rolling a 2.7-mm telescope into the middle meatus, as is frequently recommended in adults, is virtually impossible in children.

The physical examination, therefore, gives clues to the diagnosis of possible sinusitis but is not diagnostic.

OTHER DIAGNOSTIC AIDS

Table 97.4 lists other diagnostic modalities useful in the evaluation. Transillumination in children is useless as the sinuses are quite small, do not transilluminate, and offer no diagnostic advantages. Ultrasound can be used only in the maxillary sinus and has been found to be inconsistent with plain radiography. Plain films have been found to be inaccurate when compared to computed tomography (CT) scans (Fig. 97.1). McAlister et al. (6) at St. Louis Children's Hospital prospectively studied 70 children with symptoms of chronic sinusitis and compared the plain films with the coronal CT scans. They found a discrepancy between CT scans and plain films of 29% to 23% and concluded that the plain films both over- and underestimate the amount of sinus disease noted on CT scans. Similar findings have been reported by Lazar et al. (7) and Goldstein and Phillips (8). CT scan has become the gold standard for the

TABLE 97.4 OTHER DIAGNOSTIC AIDS FOR PEDIATRIC CHRONIC SINUSITIS

Transillumination: No help in children
Ultrasound: Not a viable option
Plain films: Inaccurate assessment of ethmoid sinuses
CT scan: Most accurate assessment of the sinuses
MRI applicable for acute disease extending beyond sinuses; into the orbit and brain

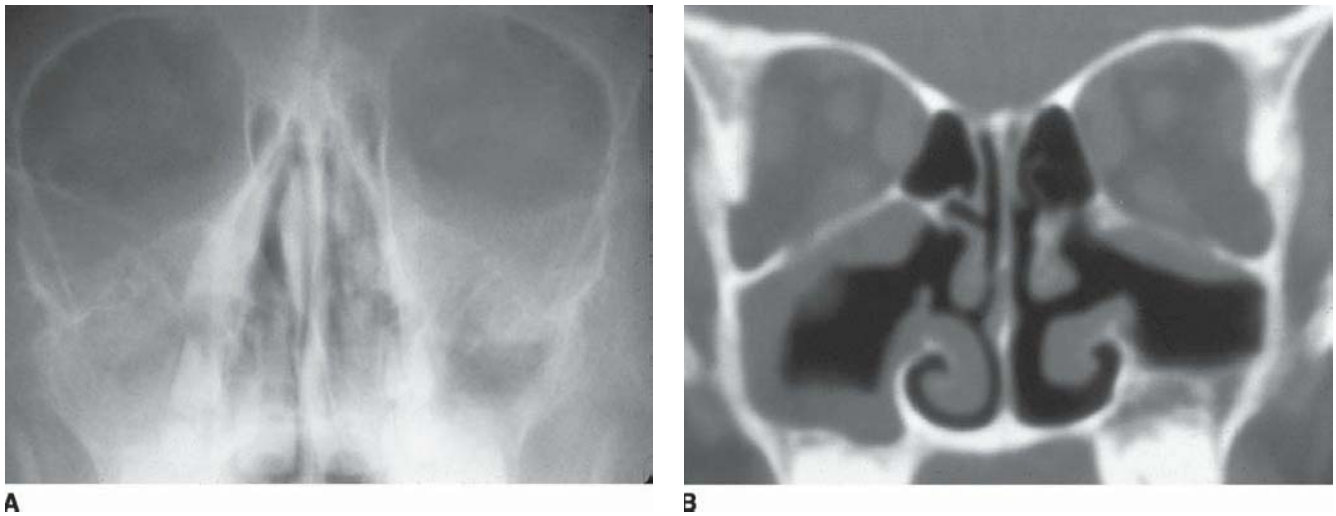

Figure 97.1 **A:** Plain radiograph of a child who has had endoscopic sinus surgery. Notice the opacification of the right maxillary sinus and significant mucous membrane thickening of the left maxillary sinus. The ethmoid sinuses are difficult to assess on this film. **B:** Computed tomography scan of the same patient, taken about 20 minutes later. No disease is seen in the ethmoid cells, and true mucous membrane thickening of the right maxillary sinus was represented as opacification on the plain films. The right maxillary sinus is clear, except for thickening along the roof of the sinus. Note that the maxillary antrostomies are widely patent.

evaluation of chronic sinusitis in children. There is increasing concern that children are receiving significant doses of radiation from CT scans. Brenner et al. (9) raised the concern that radiation in infants increased the risk of cancer later in life. This was highly controversial; however, Rogers (10) noted that children were getting doses similar to adults and the smaller heads were associated with greater doses of radiation (11). This is particularly important when it is understood that 25% to 30% of a child's bone marrow is located in the skull. Pediatric radiologists are acutely aware of this issue and now practice ALARA or "as low as reasonably achievable" to obtain the desired results.

ETIOLOGY

Our understanding of the etiology of chronic sinusitis continues to evolve. A principle that is now a cornerstone in our understanding of chronic sinusitis is that initially an inflammatory obstruction occurs in the natural ostium of the sinuses. The cause of the inflammation may be multifactorial but is usually secondary to a viral or bacterial infection. An area that appears particularly prone to obstruction is the ostiomeatal complex. This narrow channel, the infundibulum, drains the frontal, anterior ethmoid, and maxillary sinuses. The infundibulum is bordered by the uncinate process anteriorly and arches posteriorly where it is bordered by the ethmoid bulla. The frontal sinuses drain most frequently into the superior portion, and the maxillary sinuses drain into the posterior half of the infundibulum. Edema from any cause can narrow the infundibulum or the ostium and cause obstruction, which could result in a secondary infection. The viruses most frequently encountered are in patients with acute sinusitis: rhinovirus, parainfluenza, influenza, and adenovirus. The obstruction may be secondary to anatomic abnormalities or inflammation secondary to upper respiratory tract infections, allergies, or barotrauma. It was thought for many years that an anatomic variation of the anatomy around the ostiomeatal complex is associated with a higher incidence of chronic sinusitis. Children with septal deviations, paradoxical turbinates, and infraorbital cells do not have a higher incidence of chronic sinusitis (12–14).

We know that normal ciliary function is necessary for healthy sinuses; we also know that chronic sinusitis is associated with abnormal cilia. The cilia beat more slowly and less efficiently in patients with mucosal infections. When two ciliated surfaces come together, a localized disruption of the ciliary clearance and a secondary pooling of secretions occur. In the area of the ostium, the secretions may become secondarily infected and cause an acute or chronic sinusitis. Ciliary function is important because the ostia are often small and located in positions that are not conducive to spontaneous drainage. The best example of this is the maxillary sinus, where the ostium is located at the superior medial border. Kartagener syndrome is an example of significant ciliary dysfunction, and virtually all of these patients have evidence of chronic sinusitis. Some investigators believe that gastroesophageal reflux disease (GERD) plays a vital role in the etiology of chronic sinusitis. Barbero (15) noted that the parallel existence of upper airway inflammation, intractable sinusitis, and gastroesophageal reflux suggests a causal relation. Another possible explanation is GERD causes interruption of the normal mucosa over the adenoid pad allowing the formation of

biofilms deep within the crypts of adenoid tissue. This in turn could be associated with a nidus for seeding of the nose with pathologic bacteria. It is likely that a relation exists between GERD and sinusitis in some patients, but the overall frequency is not understood. The presumed etiology for this association is once again inflammation followed by ostial obstruction and subsequent infection. Gastric secretions are very caustic to nasal mucosa, and only occasional, once every few days, regurgitation may be enough to result in a diseased state. Infrequent exposure will not be noted with our current methods of diagnosis.

Most episodes of sinusitis occur during the winter when viral upper respiratory tract infections are at their greatest. This lack of correlation with the incidence of peak allergy calls into question the overall role of allergies in sinusitis. In some patients, seasonal allergy plays a role. Environmental and food allergies, which are not seasonal, may also play a significant role in some patients. A variety of immune deficiencies and ciliary dysfunction also may be associated with chronic sinusitis.

BACTERIOLOGY

Despite the importance of sinusitis, relatively few studies investigated the microbiology of chronic sinusitis in children. This is probably because of the inaccessibility of the sinuses except the maxillary, which is accessible through a puncture but requires a general anesthetic in younger patients.

The literature focusing on chronic versus acute sinusitis is inadequate, but some useful information can be ascertained from studies performed on acute sinusitis. Investigations of acute sinusitis found that *Streptococcus pneumoniae* was the most common organism (30%), followed closely by *Moraxella catarrhalis* and *Haemophilus influenzae* (20%). *H. influenzae* is usually nontypeable. Both *M. catarrhalis and H. influenzae* have a high incidence of β-lactamase–producing enzymes and are therefore resistant to many antibiotics. Anaerobes were infrequently found (only one in 79 sinus aspirates), and *Staphylococcus* also was rare. One-fourth of patients with bilateral maxillary sinusitis had discordant bacterial cultures. Because the cultures were taken about 10 days after the onset of symptoms, viruses were not often found. The bacteria involved with subacute infections (i.e., infections lasting between 10 and 21 days) are similar to those of acute sinusitis, with *S. pneumoniae*, *M. catarrhalis*, and *H. influenzae* being the most common (Table 97.5).

The bacteria of chronic sinusitis are similar, with notable exceptions. Brooks et al. (16) found a high incidence (~50%) of anaerobic bacteria in the culture of maxillary sinus contents. Most of the anaerobes were anaerobic cocci and *Bacteroides* sp. Nord (17) also cultured only the maxillary sinus and found a high incidence of anaerobic bacteria. The use of broad-spectrum antibiotics has resulted in an increase in the incidence of resistant bacteria of the upper respiratory tract. There is evidence that *H. influenzae* is now much more resistant to ampicillin in pediatric rhinosinusitis (18). There is also an increase in the incidence of *S. pneumoniae* serotype 19A, which has an unusually high resistance rate (19). There are also multiple studies reporting an increased incidence of MRSA-positive cultures (20–22). PCV7 vaccinations have resulted in vaccine-specific serotype eradication of bacteria, but there has been a shift to other resistant *H. influenzae*–resistant strains (23).

Peptococci
Peptostreptococci
Bacteroides

MEDICAL MANAGEMENT

Mechanical cleaning of the nasal airway with saline irrigation is increasingly recognized as a valuable factor in treatment of chronic sinusitis (24,25). The problem is patient compliance in the pediatric age group. Kassel et al. (26) reported, in a metaanalysis report, a 40% incidence of noncompliance. Studies however have failed to show that it helps with acute sinusitis (27). There is a general consensus that buffered normal saline is better for ciliary function and therefore is preferable to hypertonic solutions. Treatment for other possible causes of sinusitis, including allergies and immune deficiencies, should also be instituted before endoscopic sinus surgery. In a recent questionnaire of pediatric otolaryngologists (28), the cornerstones for the medical management of chronic sinusitis continue to be prolonged broad-spectrum antibiotic therapy, irrigation with normal saline, and topical nasal steroid sprays. Currently, the oral antimicrobial classes used to treat acute rhinosinusitis include b-lactams, fluoroquinolones, macrolides/azalides, lincosamides, and sulfonamides/trimethoprim with one ketolide as a possibility (Table 97.6). A complete discussion of these classes of antibiotics is beyond the scope of this chapter but can be found in the Supplement to *Otolaryngology—Head and Neck Surgery*, Antimicrobial Treatment Guidelines for Acute Bacterial Rhinosinusitis (29). Antibiotics should be reserved for patients with bacterial infection, with the goal of eradicating the pathogen from the site of infection.

TABLE 97.6 MEDICAL MANAGEMENT OF PEDIATRIC SINUSITIS

Antimicrobial Dosage

Amoxicillin (90 mg/kg/d) in three divided doses
Amoxicillin clavulanate (Augmentin), 90 mg/kg/d every 12 h of 600 mg/5 mL suspension
Erythromycin–sulfisoxazole (Pediazole), 50/150 mg/kg/d in four divided doses
Sulfamethoxazole–trimethoprim (Sulfa or Bactrim), 40/8 mg/kg/d in divided doses
Cefuroxime axetil (Ceftin), 30 mg/kg/d in two divided doses
Cefprozil (Cefzil), 30 mg/kg/d in two divided doses
Cefpodoxime proxetil (Vantin), 10 mg/kg/d in two divided doses
Clindamycin (Cleocin), 30 mg/kg/d in four divided doses
Clarithromycin (Biaxin), 15 mg/kg/d in two divided doses
Azithromycin (Zithromax), 10 mg/kg/d in one loaded dose

The current recommendations for treatment of pediatric patients with mild disease and who have not received antibiotics in the previous 4 to 6 weeks would include high-dose amoxicillin (90 mg/kg/day) in three divided doses or amoxicillin/clavulanate (90 mg/kg/day every 12 hours of 600 mg/5 mL suspension), cefpodoxime proxetil, cefuroxime axetil, or cefdinir (29). If the patient has a history of immediate type I hypersensitivity to the b-lactams, then consider trimethoprim/sulfamethoxazole (TMP/SMX), azithromycin, clarithromycin, or erythromycin. If the patient has received antibiotics within the past 4 to 6 weeks, then consider high-dose amoxicillin/clavulanate (90 mg/6.4 mg/kg/day), cefdinir, cefpodoxime proxetil, or cefuroxime axetil. If the patient is type I hypersensitive, then consider the same alternatives. At times, combined therapy is appropriate. Examples of combined therapy include high-dose amoxicillin or clindamycin plus cefixime or rifampin. Rifampin should not be used as monotherapy for longer than 10 to 14 days, as resistance can occur rapidly (29).

The treatment of acute and recurrent sinusitis should cover *S. pneumoniae, M. catarrhalis,* and *H. influenzae*. These three bacteria account for 70% of the bacteria causing sinusitis. One hundred percent of the *M. catarrhalis* and thirty to fifty percent of the *H. influenzae* bacteria are β-lactamase producers; for this reason, the antibiotic selected should cover the β-lactamase producers. The appropriate duration of antibiotic therapy still has not been systematically studied in children and is based on otitis media investigations. Empirically, acute sinusitis is usually treated for 10 to 14 days, if there is improvement of symptoms within 48 to 72 hours. Symptoms may last for up to 3 weeks even if adequately treated. If significant improvement has not occurred by then, an alternative antibiotic should be used. If the patient is not asymptomatic at the end of the first course of treatment, then the antibiotic should be continued for 7 to 10 more days.

No studies have evaluated the efficacy of prophylactic antibiotics in the treatment of recurrent or chronic sinusitis. Our current practice is to use a broad-spectrum antibiotic that would cover the bacteria of acute sinusitis as well as *Streptococcus* and *S. aureus* for 3 weeks (see Table 97.5). It is tempting to use prophylactic antibiotics; however, this should be used very sparingly because it may be a significant cause for emerging resistant bacteria. Rifampin, loracarbef, clindamycin, and TMP/SMX have been found to be effective against the penicillin-resistant strains of *S. pneumoniae*.

The role of anaerobes is unclear but should be considered in patients with chronic sinusitis. Gram-positive anaerobic streptococci and staphylococci are generally penicillin susceptible and therefore present no medical therapeutic problems. Gram-negative *Bacteroides* species producing β-lactamase respond nicely to amoxicillin/ potassium clavulanate (30). As a general rule, very few otolaryngologists are using IV antibiotics to treat chronic sinusitis (28).

Adjunctive medical modalities such as antihistamines, topical or oral decongestants, topical or oral steroids, and anti-inflammatory agents have not been studied in children or adults. Topical nasal steroid sprays are used on a regular basis (28) and are considered to be very safe.

SURGICAL MANAGEMENT

There is now general consensus regarding the surgical management of chronic sinusitis in children. Virtually all pediatric otolaryngologists would recommend adenoidectomy as a first step, and many would perform it prior to embarking on a complete workup for allergies or immune system assessment (28). The following surgical modalities have been used to treat chronic pediatric sinusitis (Table 97.7).

Adenoidectomy

Previous investigations have shown an association between children with diseased tonsils and adenoids and evidence of sinusitis. It is obvious that the removal of a large obstructive adenoid pad would be an appropriate initial mode of therapy to see if the symptoms abate (Fig. 97.2). There

TABLE 97.7 SURGICAL MANAGEMENT OF PEDIATRIC CHRONIC SINUSITIS

Questionable efficacy
Tonsillectomy
Antral lavage
Inferior meatal antrostomy

Probable efficacy
Adenoidectomy (as a first treatment) 70% successful
Middle meatal antrostomy/possibly balloon sinuplasty
Anterior or anterior and posterior ethmoidectomy
Frontal sinuses are not developed and sphenoid is rarely diseased in children.

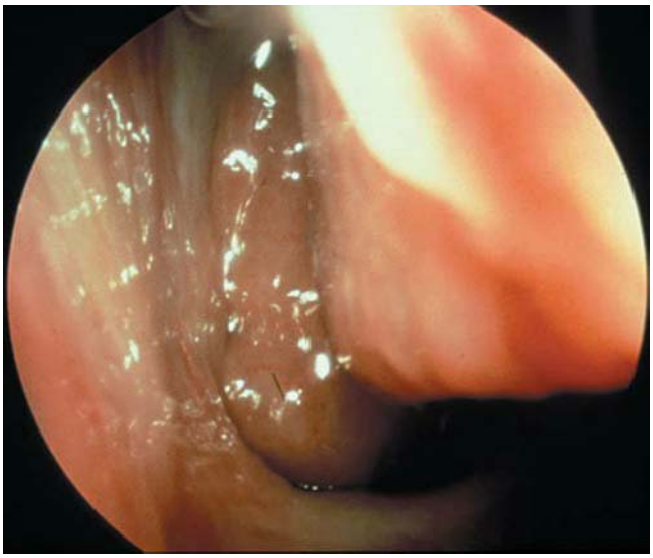

Figure 97.2 Adenoid enlargement.

is now general agreement that removal of even a small adenoid pad will decrease symptoms. The reason was not obvious until biofilms were noted on and in the crypts of the adenoid pad in children with chronic sinusitis (31–34). Brietzke and Brigger (35) in a metaanalysis noted significantly improved symptoms in 69.3% of patients after an adenoidectomy. It would therefore appear to be appropriate to perform an adenoidectomy in children who are not adequately managed with aggressive medical management.

Antral Lavage

Antral lavage has been described as a method to both detect and treat recurrent sinusitis. One of its obvious deficiencies is that it addresses only the maxillary sinus. The lavage can be performed through the natural ostium, the inferior meatus, or the canine fossa. There is now renewed interest in lavage with newer tools to cannulate the natural ostium of the maxillary sinus and provide more aggressive cleaning of the cavity (36). The studies are too few to make any recommendations about the efficacy of these techniques.

Inferior Meatal Antrostomy or Nasal Antral Windows

At one time, nasal antral windows were the mainstay of surgical management of chronic rhinosinusitis. The procedure is now rarely used except in children with underlying immunodeficiency, AIDS, and in some cases of cystic fibrosis. Muntz and Lusk (37) performed a retrospective evaluation in 39 children who were treated with bilateral inferior meatal antrostomies for chronic sinusitis and found that symptoms were not controlled in 60% of patients at 1 month and 73% at 6 months. We therefore abandoned the procedure in children.

Middle Meatal Antrostomy

An alternative mechanism for ventilating the maxillary antrum is to open the natural ostium through a middle meatal antrostomy. Ostrum was cited by Wilkerson (38) as the first investigator in the United States to make a case forcefully for limited middle meatal antrostomy. Hilding (39) did a series of experiments creating maxillary antral windows at different sites in rabbits and concluded that the infection rate would be higher if the natural ostium were opened. On the basis of these findings, it became heresy to open the natural ostium of the maxillary sinus. Wilkerson (38) rekindled interest in the middle meatal antrostomy and showed that it was effective in treating some patients with chronic sinusitis. There is now good evidence that the middle meatal antrostomy can be safely operated on and remains patent. Failure to identify the natural ostium or enlarge it can result in persistent obstruction and persistent disease. A new technique of opening the natural ostium of sinus with a high-pressure balloon has been introduced in adults and is starting to be investigated in children. At this point in time, 55% of pediatric otolaryngologists have been trained in the use of balloons, but only 7% use it occasionally and no one is using it routinely. Ramadan has performed most of the studies to date, and (40–42) the results are encouraging; however, they have not been reproduced at other centers. Randomized studies will be required to assess the efficacy and cost-effectiveness of using the new tool. In children, the only place it would be efficacious would be in the maxillary sinus as the frontals are not developed, the sphenoid sinuses are rarely diseased, and the technology is not applicable in the ethmoid sinuses.

Ethmoidectomy

Ethmoidectomy has gained wide acceptance as an acceptable method for managing medically intractable chronic rhinosinusitis in adults and children. It can be performed through the external, intranasal, or transantral approaches. With the advent of the Hopkins rod-lens system, endoscopic ethmoidectomy has become the standard procedure and allowed ethmoidectomy to be safely performed in children. The role of endoscopic ethmoidectomy in children continues to be clarified but is accepted as a viable option in refractory chronic sinusitis. Gross et al. (43) and Lusk and Muntz (44) established that endoscopic ethmoidectomy could be safely performed and was effective in children. Extensive sphenoethmoidectomy is usually not justified in children unless they have symptomatic polyps secondary to cystic fibrosis, allergic fungal sinusitis, or nonallergic rhinitis with eosinophilia syndrome (NARES). Anterior ethmoidectomy and a small maxillary sinus antrostomy is usually all that is needed in children. The posterior ethmoid and sphenoid sinuses are not usually involved; therefore, a more limited or conservative procedure is appropriate. Most pediatric otolaryngologists will

only do an anterior ethmoidectomy and maxillary antrostomy initially (28). Terris and Davidson (45) reviewed the adult and pediatric literature for endoscopic sinus surgery and found 1,713 patients who had undergone surgery and 91% who were improved. Hebert and Bent (46) did a meta-analysis of endoscopic sinus surgery in children and noted a uniformly high rate of success. Chang (19) found an 86% overall satisfactory rate from surgery when it was assessed by the parents. Individual symptom improvements were as follows: nasal obstruction, 91%; purulent rhinorrhea, 90%; postnasal drip, 90%; headache, 97%; hyposmia, 89%; and chronic cough, 96%. This study was confined to Asian children. The use of absorbable stenting material such as Merogel (Medtronics, Minneapolis, MN) has been felt by some to decreased the need for a secondary look because it is thought to decrease scarring (47,48). It is to be placed into the cavity dry (Fig. 97.3) and then injected with 2 to 4 mL of normal saline to promote absorption within 2 weeks. If the stent is not injected with saline, it will remain in the cavity longer than desired. Sobol et al. (49) reported that only 15% of pediatric endoscopists were using stents in 2005; however, this trend has reversed somewhat and 38% of endoscopists are now using some kind of absorbable stent (28). Thirty-six percent never use absorbable stents in children. Very few endoscopists, 11%, are now doing second looks with a general anesthetic (28).

Figure 97.3 Bioresorbable nasal dressing (MeroGel) placed in the middle meatus.

The ethmoid cavity in children is narrow, and it can be difficult to know exactly where you are. The safety of revision endoscopic sinus surgery and extensive sinus surgery required for cystic fibrosis has been enhanced with the use of guided imaging (Fig. 97.4). Guided imaging is now being used more frequently; however, there is no consensus as to when it is appropriate.

Facial Growth

Animal studies in piglets (50,51) led to the suspicion that endoscopic sinus surgery could lead to an interruption of facial growth. The first study to mention facial growth as an issue in children was Wolf in 1995 and he noted no interruption of facial growth in children (52). Senior (53) compared children with unilateral ethmoidectomy for orbital cellulitis 7 years after their intervention. He compared these patients to normal adults and adults with a history of sinusitis and noted no significant variation in the size of the maxillary or ethmoid sinuses. Bothwell et al. (54) examined facial growth in children who had endoscopic sinus surgery at a mean age of 3.1 years. Sixty-seven children who had endoscopic sinus surgery were examined for interruption of facial growth 10 years later at a mean age of 13.2 years. Forty-six children who had endoscopic sinus surgery were compared with twenty-one children who had chronic sinusitis but did not have surgery. Quantitative anthropomorphic analysis was performed by using 12 standard facial measurements, and a facial plastic surgery expert performed qualitative facial analysis. With these parameters, no evidence was found that endoscopic sinus surgery affected facial growth as compared with children with endoscopic sinus surgery, children with chronic sinusitis, and the normal population.

COMPLICATIONS

Table 97.8 summarizes complications of sinusitis.

Orbital Complications

Complications of acute and chronic sinusitis are best recognized and treated early. Most of the complications arise from acute sinus infections and extend into the adjacent orbit and cranial cavities. A bimodal distribution of orbital and intracranial complications is found. Orbital complications are more common in younger children, have significant morbidity, and are potentially life-threatening. Children younger than 7 years are more readily treated with aggressive medical management, whereas older children are more likely to require surgical intervention and have intracranial complications. For children aged 7 years and older, magnetic resonance imaging (MRI) in addition to CT scans should be performed to assess for intracranial disease (Fig. 97.5). Infections from the sinus can spread to the orbit through the arteries, veins, or lymphatics but most often spread by direct extension through a dehiscence in the lamina papyracea (Fig. 97.6A and B).

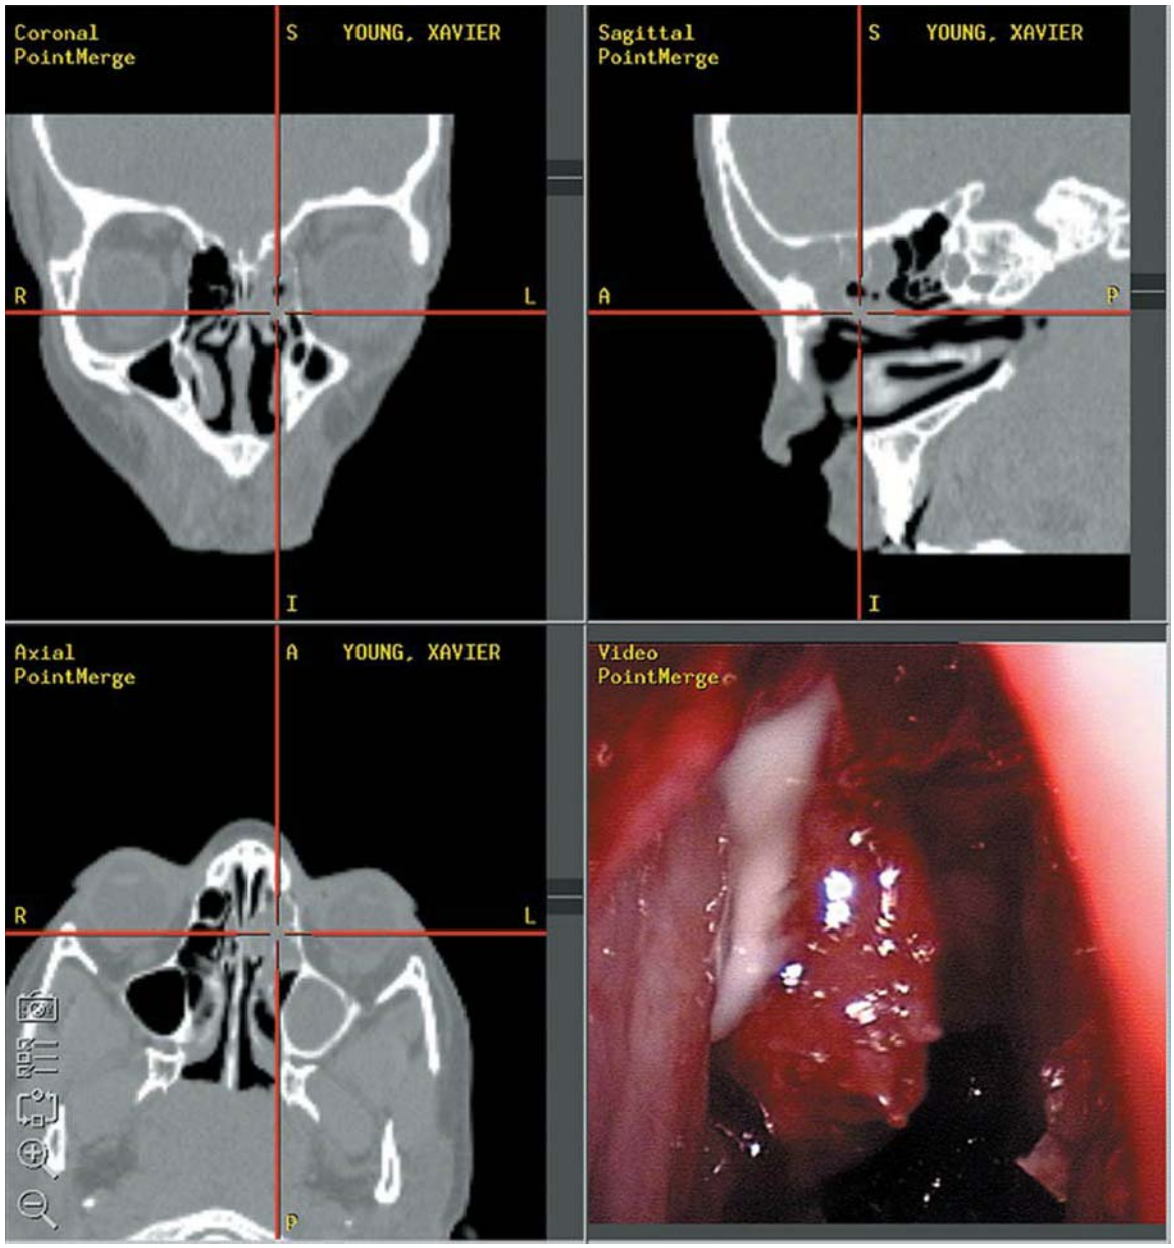

Figure 97.4 Guided imaging in children; probe in the sphenoid sinus.

The signs and symptoms of orbital complications can be used to stage the disease and guide management. The time-honored classification proposed by Chandler and colleagues has gained the widest acceptance.

Group 1: Inflammatory (preseptal) edema of eyelids without tenderness, obstruction of venous drainage, no associated visual loss or limitation of ocular movements

Group 2: Orbital cellulitis with diffuse edema of the adipose tissue in the orbital contents secondary to inflammation and bacterial infections, no abscess formation

Group 3: Subperiosteal abscess; abscess formation between the orbital periosteum and the bony orbital wall. The mass displaces the globe in the opposite direction (usually down and lateral); the proptosis may be severe with decreased ocular mobility and visual acuity. The abscess may rupture into the orbit through the orbital septum.

Group 4: Orbital abscess; a discrete abscess within the orbit. Proptosis is usually severe but is symmetrical and not displaced, as in the subperiosteal abscess. Complete ophthalmoplegia results, and visual loss occurs in 13%.

Group 5: Cavernous sinus thrombosis; progression of the phlebitis into the cavernous sinus and to the opposite side, resulting in bilateral symptoms.

These stages are important because they help specify the treatment and define the prognosis.

TABLE 97.8 PERSISTENT SINUS DISEASE

Orbital complications
- Orbital inflammation (preseptal)
- Orbital cellulitis
- Subperiosteal abscess
- Orbital abscess
- Cavernous sinus thrombosis
- Blindness

Intracranial complications
- Meningitis
- Epidural abscess
- Subdural abscess
- Acute and chronic brain abscess

The physical examination is important. Proptosis can occur with any inflammatory reaction within the orbit. If the proptosis is symmetrical, the entire orbit is likely to be involved, but if it is asymmetrical, a mass in the opposite quadrant is likely to be causing the proptosis. In general, the greater the proptosis, the greater the pressure and the more severe, and therefore, the more dangerous the infection. The axial CT scan is the best method of diagnosing subperiosteal and orbital abscesses. Cavernous sinusitis is rare but does occur in children.

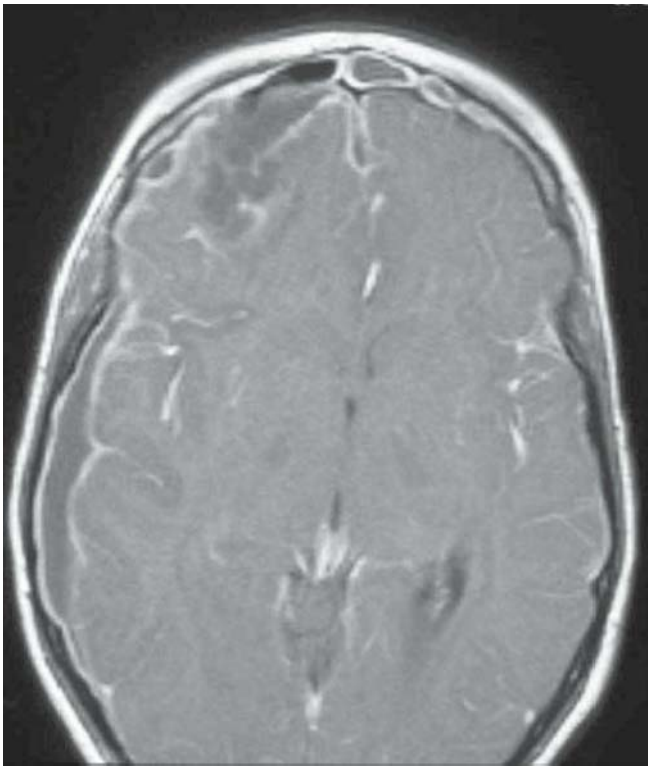

Figure 97.5 MRI scan of patient with frontal sinusitis and epidural abscess.

If the infection originates in the sinuses, the most likely causes are the bacteria that cause acute sinusitis: *S. pneumoniae*, *H. influenzae*, *M. catarrhalis*, and *S. pyogenes*. *Staphylococcus aureus* is more likely to occur with chronic infections and in the older child. Intracranial complications are most likely to be associated with *Streptococcus* species and *Staphylococcus*. MRSA is becoming a more significant and resistant cause of the intracranial and intraorbital complications (55).

Progressive loss of visual acuity is a symptom that demands rapid investigation and intervention. The visual loss can be secondary to direct pressure on the optic nerve or secondary to neuritis. Regardless of the cause, when the abscess is drained, the visual loss usually reverses rapidly.

Orbital cellulitis and abscesses are potentially life-threatening infections. Managing these complications requires the expertise of many specialists. Medical management starts with aggressive intravenous antibiotics that cross the blood–brain barrier to prevent intracranial infections. The signs and symptoms of fever, motility, and visual acuity are carefully monitored. If no improvement is seen after 24 hours of intravenous antibiotics or if the patient's clinical status worsens, an axial CT scan is performed to identify a possible abscess. If one is found, it is surgically drained. If a decrease in visual acuity is noted, immediate evaluation and surgical intervention are implemented. Arjmand et al. (56) recommended removing a larger portion of the lamina papyracea for drainage. Manning (57) recommended removing a much smaller portion of the lamina papyracea, with equally good results. It now appears that subperiosteal abscess can be safely drained endoscopically. Children recover quicker with endoscopic drainage, and the hospital stay is approximately half of that with using an external approach (56). The endoscopic approach in an acutely infected sinus is technically more difficult but is associated with a lower incidence of complications than is the external approach. Each surgeon will have to decide which procedure is the most efficacious and safest.

An orbital infection that extends posteriorly into the cavernous sinus is very dangerous and has significant sequelae (58). Most of the patients with this complication secondary to sinusitis have involvement of the sphenoid sinus, which frequently extends into the ethmoid sinuses. The signs and symptoms of cavernous sinus thrombophlebitis are similar to those already mentioned for orbital cellulitis, abscess, or subperiosteal abscess. If cavernous sinus thrombosis or intracranial complications are suspected, an emergency axial CT scan and MRI with contrast are indicated. If cavernous sinus thrombosis is present, the CT scan will show a lack of contrast enhancement in one or both cavernous sinuses. Aggressive intravenous antibiotic therapy should be directed toward gram-positive cocci (*S. aureus*) and gram-negative bacilli with a third-generation cephalosporin such as cefuroxime axetil. If the sphenoid sinus is involved, it should be drained through the ethmoid sinus.

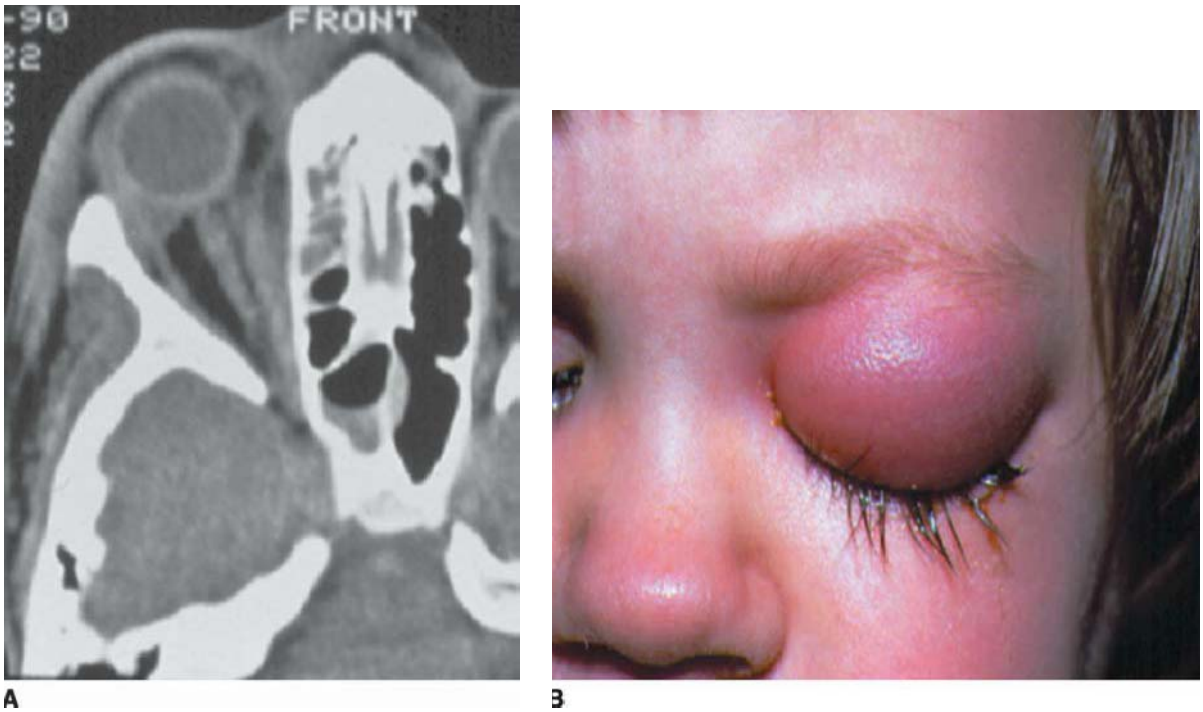

Figure 97.6 **A:** Computed tomography image of same patient with frontal sinusitis and epidural abscess. **B:** Clinical photograph of patient.

Intracranial Complications

Intracranial complications include meningitis and epidural, subdural, and acute or chronic brain abscess. Brain abscesses are the most common intracranial complications with sinusitis and are exceeded in overall frequency only by orbital complications. Patients most frequently present with headaches (92%), fever (85%), and nausea and vomiting (62%) (59). The most common form of abscess is the subdural, followed closely by the frontal lobe abscess or a combination of the two. Intracranial sequelae are most likely to occur in older children or adults, and in male patients (60), the incidence varies with location. Brain abscesses and inflammation are most readily identified with an MRI and are most likely to occur in the frontal lobes (60). These are particularly silent and may be difficult to diagnose on clinical grounds. Many of the patients have no signs of increased intracranial pressure. Symptoms of intracranial pressure include bradycardia, papilledema (this may not be present, as it takes some time to develop), stiff neck, hypertension, nausea, vomiting, and decreased consciousness. A dilated pupil is an ominous sign and suggests transtentorial herniation. Common symptoms of intracranial abscess include fever, headache, behavioral changes, seizures, nuchal rigidity, focal neurologic signs, and occasionally photophobia. Patients with epidural abscess generally are first seen with a continuous dull headache, sudden elevation of temperature, and clear cerebrospinal fluid (CSF). Patients with subdural abscesses are toxic, with changes in mental status, severe headaches, nuchal rigidity, focal neurologic changes, papilledema, and cloudy CSF with leukocytes, but no bacteria or positive cultures. These abscesses are thought to be the most dangerous intracranial complications and require emergency surgery.

Intracranial abscesses involve the same pathogens as ear infections and acute sinusitis (*S. pneumoniae*, *H. influenzae*, and *M. catarrhalis*). Chronic sinusitis is associated with a much higher incidence of *S. aureus* and a-hemolytic streptococci, which also must be covered. Medical therapy must include antibiotics that pass through the blood–brain barrier and cover the most frequently cultured bacteria. Several different regimens have been proposed: cefuroxime and metronidazole, chloramphenicol (75 to 100 mg/kg/day), and oxacillin (150 to 200 mg/kg/day).

The *Pocket Book of Pediatric Antimicrobial Therapy* recommends that until the specific etiology is identified, methicillin (150 to 200 mg/kg/day IV every 6 hours), aminoglycoside or cefotaxime (150 to 200 mg/kg/day IV every 6 hours), *and* metronidazole (30 mg/kg/day IV every 8 hours) should be used. The duration of therapy is individualized.

Medical management alone has met with variable success. Johnson et al. (61) did not cure a single patient with medical therapy, which consisted most frequently of chloramphenicol (75 to 100 mg/kg/day) and oxacillin (150 to 200 mg/kg/day). Antibiotics have the greatest chance of success if the lesion were small and the symptoms were short in duration.

Surgical management is based on the extent and location of the disease. The intracranial approach is dictated by the location of the lesion.

HIGHLIGHTS

- The signs and symptoms vary with the child's age. Purulent nasal discharge, cough, nasal obstruction, and irritability are the most common symptoms.
- The physical examination is frequently limited to anterior rhinoscopy because of the limited cooperation of the child and because of the narrow pediatric nose.
- Plain films do not define the extent of the disease and are particularly deficient in the ethmoid sinuses. Coronal CT scans are required to define the anatomy and the extent of the sinus involvement.
- The bacteria most often associated with chronic pediatric sinusitis are a-hemolytic streptococcus, *S. aureus*, *S. pneumoniae*, *M. catarrhalis*, and *H. influenzae*. MRSA is becoming more frequent and causing more complications.
- The antibiotics most often used for chronic sinusitis are amoxicillin/potassium clavulanate (Augmentin) and second-generation cephalosporins.
- Surgical modalities of questionable value are tonsillectomy, antral lavage, and inferior antral windows. Adenoidectomy is now generally accepted as the first surgical mode of therapy. Most investigators now believe that biofilms along with adenoid hypertrophy are the primary reasons for performing an adenoidectomy. The reported success rate is variable but is 67% as documented with metaanalysis studies.
- Endoscopic ethmoidectomy (anterior or anterior and posterior) and maxillary antrostomy have proven to be successful in a number of different investigators' hands and are 80% to 90% successful in controlling the symptoms of chronic sinusitis.
- Investigators are split on the use of absorbable stents; there is a general swing back toward using them.
- Second look is no longer necessary with pediatric endoscopic sinus surgery.
- Emergencies in sinusitis are usually secondary to acute sinusitis and associated with infections that extend into the orbital and intracranial cavities. These infections are potentially life-threatening and have a high incidence of morbidity.
- Large gaps remain in our knowledge of chronic sinusitis. We have not accurately defined its incidence or natural history. The etiology of sinusitis is multifactorial and complicates clinical trials. The bacterial flora must be further delineated to direct appropriate medical therapy. The duration of antibiotic therapy and the role of prophylactic antibiotics require further study.

Salivary Gland Disease in Children

98

Matthew K. Whitley *Karen B. Zur*

Pediatric salivary diseases, both benign and malignant, are not as prevalent as those in the adult population. The nonneoplastic disorders include acute and chronic inflammation (bacterial and viral), cysts, granulomatous diseases, Sjögren syndrome, sialolithiasis, and sialorrhea. Neoplastic diseases are subcategorized into mesenchymal versus epithelial and further classified as benign or malignant. This potpourri of disorders can affect the major or minor salivary glands, but predominantly the parotids and submandibular glands.

The evaluation of salivary gland pathology is the same as that done for the adult population, with emphasis placed on a thorough history and physical examination. Each of the topics discussed in this chapter addresses specific diagnostic tools to assist in the evaluation as well as the currently recommended medical or surgical intervention or both.

INFLAMMATORY CONDITIONS

Acute and chronic inflammatory diseases of the major and minor salivary glands are the most common pediatric salivary disorders (Table 98.1).

Acute Sialadenitis

Acute Bacterial Sialadenitis

Acute sialadenitis, as its name implies, is an acute inflammation of the affected gland, characterized by tenderness, localized pain, and overlying edema. Occasionally, purulent drainage may be seen emanating from the duct of the involved gland. Salivary stasis, due to either decreased saliva production or duct obstruction, increases the risk of sialadenitis. Conditions such as sialolithiasis, duct strictures, trauma, congenital sialectasis, autoimmune conditions, and dehydration contribute to stasis. Because of the serous (and therefore less bacteriostatic) composition of the parotid gland, it is more susceptible to acute suppurative sialadenitis than is the mucinous submandibular gland. During the past decade, the use of antibiotics along with fluid hydration and electrolyte management has almost eliminated the development of fulminating acute suppurative parotitis in hospitalized surgical patients. The predominant organisms include aerobic and anaerobic bacteria. Common aerobes include *Staphylococcus aureus* and *Haemophilus influenzae*, whereas the predominant anaerobes are gram-negative bacilli and *Peptostreptococcus* species (1).

The treatment is the same as that in the adult population. Local measures to increase salivary flow such as glandular massage, use of sialogogues, local heat (i.e., warm compress), and hydration complement the use of systemic antibiotics. Initial choice of antimicrobials should include a penicillinase-resistant antistaphylococcal agent that can be adjusted if no clinical improvement is seen within several days or based on culture results.

Episodes of recurrent acute sialadenitis in children often resolve by puberty (2). A conservative approach between episodes includes intermittent dilation of the ducts to avoid stricture (see section on "Recurrent Juvenile Parotitis"). Sialography can be performed in these patients to rule out duct strictures or changes in gland architecture. If chronic changes are seen, sialadenectomy should be considered. When the submandibular gland is involved, excision of the gland is recommended. When the parotid is involved, the decision-making process is complicated by the facial nerve. Various surgical alternatives have been described with limited success (3). The most effective and reliable approach is a total parotidectomy with facial nerve preservation. A superficial parotidectomy alone increases the risk of recurrent infections because of possible sialocele formation.

Neonatal Sialadenitis

Infections of the parotid and submandibular glands are rare but increasingly recognized in the premature neonate.

TABLE 98.1 DIAGNOSIS AND MANAGEMENT: DISEASES OF THE SALIVARY GLAND

Disease	Features	Management
Acute bacterial sialadenitis	Acute onset, prepubescent, purulent saliva from duct, diffuse swelling and tenderness	Hydration, sialogogues, massage, antibiotics
Neonatal sialadenitis	Warm, tender erythematous mass in neonate; expressible purulence from gland duct; *S. aureus* and *P. aeruginosa* most common	Hydration, antibiotics, avoid gland manipulation, incision and drainage if no response to antibiotics
Viral	Acute onset, similar to bacterial sialadenitis but no purulence	Symptomatic
Chronic sialectasis	Unilateral, diffuse, intermittent enlargement related to eating	Antibiotics for acute exacerbation, ductal dilation and incision, parotidectomy if refractory
Sialolithiasis	Rare in pediatric population; intermittent, unilateral pain and swelling associated with eating	Sialogogues, removal of calculus, consider extracorporeal shockwave lithotripsy
Cysts	Mostly seen in sublingual gland (ranula)	Marsupialization or excision
Granulomatous lesions	Chronic enlargement, nodularities	Treat underlying condition
Sjögren syndrome	Bilateral, symmetrical enlargement of glands; xerostomia; uncommon in pediatric population; may occur in association with other autoimmune disorders	Symptomatic, long-term follow-up
Sialorrhea	Abnormal in child older than 4 y, neurologic or mental impairment	Physiotherapy, anticholinergic/antihistamine, surgical, botulinum neurotoxin A (Botox) in some cases

The diagnosis is clinical and confirmed by a warm, tender, erythematous mass with expressible purulence from the gland's duct.

Acute suppurative sialadenitis of infancy is thought to be due to the reduction in salivary flow, immunologic immaturity, and presence of bacteria in the oral cavity of these neonates (4). Dehydration, prolonged orogastric tube feeding, and congenital anomalies of the floor of the mouth have also been associated with suppurative sialadenitis in the neonate (4). *S. aureus* and *Pseudomonas aeruginosa* are the most commonly identified pathogens. The management is similar to that of acute sialadenitis in the child and adult. Hydration and antimicrobial therapy should lead to a response within 48 to 72 hours. Unlike in the older population, it is important to avoid gland manipulation in a preterm child to reduce the risk of systemic septicemia (4). If no satisfactory improvement is seen, incision and drainage is recommended. Recurrences are uncommon.

The differential diagnosis of unilateral gland inflammation in this age group includes submandibular fat necrosis, infected lymphangioma, and cervical lymphadenitis. To confirm the diagnosis, ultrasonography can be performed but is not indicated.

Viral Sialadenitis

Mumps

Worldwide, the most common inflammatory condition affecting the parotid gland is mumps. Mumps is caused by the paramyxovirus, which has a 2- to 3-week incubation period and has been known to inflame the gonads, meninges, and pancreas as well. It is most commonly seen during the winter and spring. The contagious period occurs 2 to 3 days before the development of gland enlargement, with a prodrome characterized by malaise, fever, chills, anorexia, and a sore throat. The clinical findings are similar to those described for bacterial sialadenitis, except for the presence of purulence from the duct orifice. The management is symptomatic.

Salivary Gland Disease in the HIV Patient

Oral manifestations are one of the earliest clinical indicators of human immunodeficiency virus (HIV) infection and progression in children (5). It has been estimated that 4% of the HIV-infected children in the United States have salivary gland disease (6). Salivary gland disease in this population can be classified as enlargement, xerostomia, or both.

Salivary gland enlargement is most commonly seen in the parotid gland, followed by the sublingual and submandibular glands (7). It is characterized by a gradual growth causing facial asymmetry. Parotid enlargement has been associated with generalized lymphadenopathy and lymphoid interstitial pneumonitis, occurring between ages 4 months and 4.5 years (5). Theories abound regarding the etiology of the lymphoepithelial cysts seen in this condition. One of them posits a relation with T-lymphocyte $CD8^+$ cell infiltration in the gland (5). Some have suggested that lymphoepithelial cysts are caused by the obstruction of the salivary ducts from lymph nodes that are entrapped during parotid gland development. These benign lymphoepithelial lesions are seen initially with progressive painless

swelling of the parotid (8). In the HIV population, they are bilateral in up to 80% of cases. Parotid pseudocysts are secondary to viral inflammation and are often the initial manifestation of HIV. Testing for HIV should be done in all children with parotid cysts (8).

Treatment options should be individualized to the patient, with consideration of the risks and benefits of the proposed interventions. Most lymphoepithelial cysts will regress with antiretroviral therapy (5). Only in severe cases of salivary gland dysfunction or disfigurement is surgical intervention appropriate. The approach is cyst aspiration, partial gland excision, or doxycycline sclerotherapy (5). Sclerotherapy may be useful for growth prevention in 75% of cases and for regression of the cyst in only 25% of cases (8).

The diagnostic modality of choice in HIV patients with salivary gland enlargement is computed tomography (CT) or magnetic resonance imaging (MRI). The use of ultrasound in the evaluation of salivary gland enlargement in this population has been proposed as an alternative to conventional imaging and as a good screening tool for malignancy (in lymphoma, which appears solid). Once a malignancy has been ruled out, the management of salivary gland enlargement in the HIV population is watchful waiting (5).

Epstein-Barr Virus (EBV)

Epstein-Barr virus (EBV) infection is a known cause of infectious mononucleosis, which is transmitted through saliva. It also has been implicated in the pathogenesis of certain types of salivary gland tumors in the adult population but not in the pediatric population (9).The adenopathy of mononucleosis can involve periparotid and perisubmandibular lymph nodes.

Chronic Inflammation

The pathogenesis of the chronic salivary inflammatory disease spectrum also has changed with the interplay between sialadenitis, sialectasis, and sialolithiasis. A heterogeneous group of disorders in chronic inflammatory sialadenitis also exist, which include the group of specific and nonspecific granulomatous diseases.

Juvenile Recurrent Parotitis (JRP)

Juvenile recurrent parotitis (JRP), which was formally known as recurrent parotitis of childhood, is the most common inflammatory salivary gland disorder in children in the United States and is second only to mumps worldwide. This condition presents with recurrent inflammation and infection without a definitive etiology. The onset is generally between 3 and 6 years of age, and recurrent episodes continue throughout puberty, when the disease usually resolves. Patients present with pain and edema over the involved gland (often the parotid) and can have systemic symptoms such as fever. On physical exam, patients often have enlarged Stensen's papilla with associated yellowish plaques of protein coagulum around the opening. Treatment is medical, but sialadenoscopic washout and irrigation has also been described with success (10).

Both flexible and rigid sialadenoscopy have been used for both diagnostic and therapeutic treatment of salivary gland disorders. Small rigid scopes with working ports for saline, antibiotic, or steroid irrigation as well as for balloon dilation are available. One study of 36 patients with JRP showed a 92% recurrence-free rate at 36 months after sialadenoscopic irrigation and steroid infusion (11). Another study of six children had 100% success rate in treating recurrent infections (12). Further research is necessary to further delineate the role of this treatment modality in pediatric salivary gland disease.

Chronic Sialectasis

Chronic inflammation of the salivary glands can lead to ductal dilation, chronic salivary stasis, ascending infections, and parenchymal destruction. It is seen mostly in the adult with a history of childhood recurrent sialadenitis, sialolithiasis, and strictures. The presentation is unilateral, diffuse enlargement of the involved gland with swelling related to eating. Sialography can identify a stricture with proximal ductal dilation. The management includes a spectrum of therapies including ductal dilation or duct incision (if the stricture is distal). Conservative therapy is less effective in management of parotid sialectasis. In this situation, a parotidectomy with facial nerve preservation is required.

Because of the morbidity associated with facial nerve dissection in an inflamed field, alternative modes of therapy have been proposed. The use of botulinum toxin A to modulate parasympathetic stimulation and reduce salivary flow has been reported (13). The theory is that chemical denervation leads to atrophy of parotid gland acini.

Sialolithiasis

Relative to adults, sialolithiasis is a rare condition in the pediatric population. Relatively few cases of pediatric calculus formation in the salivary glands have been reported in the literature. In a review done in 1995, in total, 86 cases were cited. The submandibular glands are the most common site for calculus formation, followed in frequency by the parotid gland. The sublingual glands and the minor salivary glands are rarely affected. Physiologic factors such as alkaline pH, high calcium concentration, and mucin content of the saliva contribute to stone formation. Furthermore, it has been speculated that the tortuosity of Wharton duct with passage of secretions against gravity can promote stasis and calculi (14). The most common presenting symptoms include intermittent, unilateral swelling in the affected gland with ipsilateral pain, all associated with eating.

When an obstruction is suspected, radiography is 90% sensitive. In the past, panoramic and anteroposterior films were used; however, because of bony overlap of the facial

skeleton, these studies are not effective at identifying calculi. Axial CT scans are useful in identifying radiopaque sialoliths. The majority of stones can be found along the course of the ducts (Stensen's or Wharton duct) (14) with a rare occurrence of intraparenchymal stones. Most submandibular gland calculi are radiopaque, while a significant majority of parotid stones are radiolucent. Nonopaque sialoliths can be identified with ultrasonography and, in particular, color Doppler ultrasonography (15).

The underlying pathophysiology leading to stone formation is stasis secondary to either duct obstruction, decreased saliva production, or a side effect of pharmacotherapy. The most common etiology of chronic duct obstruction is mucous plugging with deposition of calcium salts. Accidental biting of Stensen's duct also can contribute to duct stricture and stasis. Decreased salivary production due to autoimmune disease is less commonly encountered in the pediatric population.

The aim of management of sialolithiasis is to restore the normal parenchymal architecture of the gland and allow its long-term functional recovery. A conservative and mostly effective mode of therapy includes stimulation of saliva production by instructing the child to suck on acidic sialogogues. In children, submandibular stones have been reported to pass out of the duct spontaneously after this maneuver. Spontaneous passage of parotid stones is less likely because of the pathway of Stensen's duct through the buccinator muscle (15).

If conservative treatment fails, alternative modes of therapy include duct dilation, sialolithotomy, or sialadenectomy. The latter is indicated if the stone is located in the posterior third of the gland or when damage to the parenchyma of the gland results in a nonfunctional gland. To evaluate this, radiographic imaging including sialography, scintigraphy, ultrasonography, and MRI can be used.

Because of the potential morbidity associated with sialolithotomy and sialadenectomy, a less invasive mode of therapy has been recently proposed. Extracorporeal electromagnetic shockwave lithotripsy (EESWL) has improved the nonsurgical approach to treatment of salivary gland calculi (15). In their report of seven patients treated with noninvasive EESWL, Ottaviani and colleagues reported complete stone disintegration in 71% of the patients and 29% partial resolution. EESWL therapy is instituted after resolution of the acute inflammatory state with antibiotics and anti-inflammatory agents. Symptom relief was observed in all patients who were studied. After an average of five sessions, all but one had complete functional recovery of the gland, as observed on scintigraphy (15). McJunkin et al. (16) recently described a case of treatment of a 2-cm parotid sialolith with a single session of lithotripsy with complete resolution.

Cysts

Mucous retention cysts are epithelium-lined cysts that result from duct obstruction. Mostly seen in the sublingual gland and presenting similar to a ranula, these true cysts involve the minor salivary glands. A ranula, in contrast, is not a true epithelium-lined cyst and represents a collection of extravasated mucin. Plunging ranulas extend below the mylohyoid muscle and can be first seen with a cervical or intraoral neck mass or both. Management is by marsupialization or excision, often in association with removal of the sublingual gland (3).

Granulomatous Lesions

Chronic salivary gland enlargement may be due to granulomatous inflammation resulting in a nodularity to the gland that must be differentiated from a neoplastic process. Tuberculosis, sarcoidosis, histoplasmosis, tularemia, cat-scratch disease, and toxoplasmosis have all been reported (3).

SALIVARY GLAND NEOPLASMS

Neoplasms of salivary gland origin are relatively uncommon in the pediatric population. They comprise 8% of all pediatric head and neck tumors, representing the fourth most frequent, after neoplasms of the nasopharynx, skin, and thyroid (17). The histologic pattern of the tumors seen in the pediatric versus adult populations is the same; however, the rate of occurrence of each subtype is different in these groups. Approximately 15% to 25% of all salivary gland tumors are malignant in adults, whereas in the pediatric population, this rate is higher, approaching 50% when vascular neoplasms are excluded (17). When including the vascular tumors in these statistics, about 35% of all salivary gland lesions in children are malignant. Thus, a solid mass identified in a child has a 2.5-fold higher rate of malignancy in comparison to a solid mass identified in an adult. Salivary gland neoplasms can be classified into benign (including the vascular lesions) and malignant tumors. The latter are subclassified into low-grade and high-grade malignancies based on histology.

Benign Mesenchymal Tumors

Benign salivary gland tumors may be of nonepithelial or epithelial origin. The mesenchymal lesions include hemangiomas (73.5% of nonepithelial tumors), lymphatic vascular malformations (18.5%), neurogenic tumors (4.2%), lipomas (1.5%), and the rarer lesions xanthoma and fibromatosis (18).

Hemangiomas account for approximately 50% to 60% of neoplasms seen in the pediatric population (19). These are nonencapsulated, often infiltrating lesions that are composed of solid masses of cells and multiple anastomosing capillaries replacing the acinar structure of the gland, while not affecting the ductal structures or the facial nerve. They appear spongy and lobulated, with a purple blush. The distribution of hemangiomas among the various salivary glands is as follows: 80% occur in parotid, 18% in the submandibular glands, and 2% in minor salivary glands

(19). Two types of hemangiomas are encountered: The capillary form is rapidly growing, present at birth, and often regresses by the age of 1 year. The cavernous form is more aggressive, appears in the older child, and has a tendency to bleed and deform. This hemangioma subtype is more difficult to manage.

The capillary hemangiomas are more commonly seen in girls, either at birth or in the first few months of life. Clinical diagnosis is the rule, and the course of resolution is almost predictable (*albeit* controversial) with conservative management. Cavernous hemangiomas are initially seen later in life. Diagnosis of salivary hemangiomas is mostly based on physical examination. Hemangiomas involving the salivary glands, specifically the parotid area, can be quite deforming. They are usually confined to the intracapsular region and may extend to the overlying skin. Ultrasound imaging may be helpful in differentiating this vascular lesion from a cystic mass but cannot define the extent of the disease. In unusual cases, an MRI may be obtained. This radiographic modality is diagnostic and can help define the limits of the mass.

Treatment of hemangiomas is not necessary if the mass is small and not involving critical organs or affecting function. In general, spontaneous involution occurs by age 4 to 6 years. In certain instances, a trial of prednisone, 3 to 5 mg/kg/day for several weeks, may serve as an effective initial course of treatment (19). A treatment protocol does not exist, but a study examining 1,109 cases of cutaneous hemangiomas (including head and neck lesions) suggested that systemic corticosteroids are effective in 36% of patients, independent of dosage, pharmacologic agents, and duration of therapy (ranging from 7 weeks with conventional-dose prednisolone regimen to 35 days of high-dose methylprednisolone regimen). According to this report, the dimension of the lesion and age at initiation of treatment are important factors affecting response to treatment. Furthermore, the authors cited a 21% rebound growth after discontinuation of systemic therapy (20). It is important to recognize that long-term systemic corticosteroid therapy is not benign. The efficacy of therapy should be questioned if no response is seen within several weeks of therapy, as systemic complications are well recognized. The indications for surgical intervention in young patients with hemangiomas are increase in tumor size, rapid tumor growth, failure of tumor to involute, and hemorrhage into the lesions.

Much interest exists in the recent literature related to the use of propranolol to treat various head and neck hemangiomas. While promising for salivary hemangiomas based on theoretical use, data are somewhat limited. Moralis et al. described a case of a 2 month old with an extensive parotid hemangioma that resolved with oral propranolol for 16 months (21). Another recent report described a large series of head and neck hemangiomas treated with propranolol, including two children with parotid lesions. Both children had good responses, although one had a relapse when treatment was discontinued 7 months into treatment (22). More research is needed to characterize the promising role of this medicine for the treatment of these particular lesions.

Lymphatic vascular malformations are the second most common benign tumors of the salivary gland. These lymphatic malformations do not replace the normal glandular parenchyma seen in the hemangiomas; rather, normal salivary gland tissue is found adjacent to the dilated lymphatic vessels. Like hemangiomas, lymphangiomas are soft, diffuse, nondiscrete lesions that become distended in the dependent position and ballotable and compressible in the upright position. They are present at birth, with about 50% to 60% of the tumors occurring before age 12 months and 90% before age 24 months. Occasionally, rapid enlargement may occur after trauma, infection, or spontaneous hemorrhage into the cyst. The histologic subtypes are macrocystic, microcystic, or mixed venous and lymphatic malformations.

Radiographic diagnosis is definitive with CT or with the classic finding of fluid/fluid levels seen on MRI. These studies can delineate the extent of disease and surrounding organ involvement. Unlike the hemangiomas, lymphatic malformations generally require surgical excision, as these lesions do not spontaneously regress. The timing of intervention is not clearly established. Intuitively, if airway compromise is observed, urgent intervention should be carried out. Otherwise, excision can be planned on a routine basis but should not be postponed later than a few years of age because of the risk that chronic infection and inflammation of the mass, especially if of parotid origin, might damage the facial nerve.

Injection of sclerosing agents has been reported, along with use of radiotherapy and electromagnetic treatment; however, these treatment alternatives have been used without significant success and with a risk of significant morbidity (23) (Table 98.2). More recent reports of the use of intralesional injections of OK-432 in treatment of macrocystic lymphatic vascular malformations of the head and neck show some response after one or two injections. OK-432 has not been approved for use in the United States by the Food and Drug Administration and is used experimentally in select US institutions.

Malignant Mesenchymal Tumors

Rhabdomyosarcoma is the most common sarcoma in children, most commonly occurring in the nasopharynx and orbit (24). It has been reported to occur in 2.1% to 3.5% of malignant salivary gland tumors in children (24,25). Usually the parotid gland is secondarily involved in cases of advanced disease and is rarely seen as a primary parotid tumor.

The classic histologic findings in rhabdomyosarcomas include the "small round blue cells" with scant cytoplasm and primitive-appearing nuclei (26). Radiographic findings on CT demonstrate heterogeneous attenuation and isoattenuation relative to muscle. The MRI findings

TABLE 98.2 DIAGNOSIS AND MANAGEMENT: BENIGN SALIVARY GLAND NEOPLASMS

Histology	Features	Management
Mesenchymal origin		
Hemangiomas	74% of mesenchymal tumors, present at birth	Observation; if symptomatic, steroids; surgical excision for complications
Lymphatic vascular malformations	19%, majority first seen by age 24 mo, distensible in dependent position	Surgical excision, sclerosing agents—not widely accepted
Epithelial origin		
Pleomorphic (mixed) adenoma	Slow growing, painless, freely mobile	Parotidectomy with facial nerve preservation
Warthin tumor	Parotid; unilateral, multifocal, painless mass; often cystic	Parotidectomy with facial nerve preservation
Oncocytoma	Mitochondria rich	Surgical excision
Monomorphic adenoma	Rare; slow growing	Surgical excision

typically reveal a heterogeneous mass with ill-defined borders, isointense to muscle, and diffusely enhancing after contrast administration (26).

The diagnosis of rhabdomyosarcomas is confirmed by fine-needle aspiration (FNA), incisional biopsy, or both. Definitive therapy includes a combination of interventions in variable order based on treatment protocols. The surgical approach includes sialadenectomy, wide local resection of involved tissue (mandible, skin, muscle), and limited lymph node dissection, if indicated (25). Radiation therapy and chemotherapy protocols exist and should be administered based on local practices. They include adjuvant chemotherapy and radiation therapy, induction chemotherapy followed by surgery and postoperative radiation and additional chemotherapy, and induction chemotherapy with additional postoperative chemotherapy (25) (Table 98.3).

Epithelial Neoplasms

After excluding the clinically evident mesenchymal tumors, solid salivary gland masses are difficult to evaluate in children (19). In general, the history, physical findings, radiologic studies, skin tests, serologic results, and FNA biopsy findings may suggest a disease process, but diagnostic certainty is almost always achieved after excision of the tumor (19). It was found that in respect to pediatric salivary neoplasms, the higher or larger the gland, the higher the likelihood of malignancy. This relation is inverse compared with that known in the adult population (17,26). The parotid gland is the predominant location for salivary tumors (65.8%), and the majority of these tumors are malignant (80%) (17).

The presentation most commonly seen in patients with salivary gland tumors is a mass lesion. In a series of pediatric parotid tumors reported by the Massachusetts Eye and Ear Infirmary, 89% of neoplasms were found at the angle of the mandible; none of these were in association with cervical adenopathy (19).

The evaluation of a solitary mass of the salivary gland should include a thorough history and physical examination. Discussion in this chapter is focused on the parotid gland because it is the most likely site of tumor involvement in the child. In many situations, radiographic imaging techniques can provide a high degree of specificity that can be used to guide therapy and to plan a surgical approach. The merits of each diagnostic modality are described in association with the particular pathologic entities described. In general, ultrasonography may be used to assess the size of the parotid gland, distinguish diffuse from focal disease, assess vascularity and adjacent vascular structures, distinguish cystic from solid lesions, and guide FNA.

However, contrast-enhanced CT and MRI provide more accurate and diagnostic information. In most pediatric parotid diseases, especially when an inflammatory condition is suspected, CT is the modality of choice. CT has the ability to detect calcium deposits with tenfold sensitivity over plain films. Solitary or multiple calcifications usually indicate the presence of chronic sialadenitis. If calcification is seen within the gland's parenchyma but not within a mass, then the most likely condition is a chronic inflammatory process. If, conversely, the calcification is within a salivary gland mass, the lesion is most commonly a pleomorphic adenoma (27).

MRI is useful in situations in which a cranial neuropathy (specifically, involving the facial nerve) or a nonpalpable mass is found. This modality often shows the margins of a salivary gland mass more sharply than does the CT scan. Controversy still exists in regard to indications for use of the CT scan versus the MRI in salivary masses (27).

After radiographic evaluation of the solitary salivary gland mass, cytologic examination is useful in distinguishing tumor from inflammation and in recognizing a malignant tumor from a benign one. The sensitivity in detecting the presence of a salivary gland tumor by using FNA is

TABLE 98.3 DIAGNOSIS AND MANAGEMENT: MALIGNANT SALIVARY GLAND NEOPLASMS

Histology	Features	Management
Mesenchymal origin		
Rhabdomyosarcoma	Most common sarcoma in children, "small blue cells," parotid secondarily involved	Combined surgery, radiation, and chemotherapy in any order
Epithelial origin		
Mucoepidermoid carcinoma (MEC)	Majority of salivary gland malignancies; cystic or solid; low, intermediate, high grade	Wide local excision or total parotidectomy with facial nerve preservation; no clear indication for elective neck dissection, modified neck dissection for clinical nodes, no established protocols for postoperative radiation or chemotherapy
Acinic cell carcinoma	Second most common malignancy, 90% 5-yr survival with combined therapy	Wide local excision with facial nerve preservation, adjuvant chemotherapy reported, possible postoperative radiation
Adenocarcinoma	Solid mass	Wide local excision with facial nerve preservation, adjuvant chemotherapy reported
Undifferentiated carcinoma	Poor prognosis	Parotidectomy with facial nerve preservation unless obviously involved
Adenoid cystic carcinoma	Rare in children, neurotrophic	Wide local excision, consider facial nerve resection/biopsy if suggestive, chemotherapy
Squamous cell carcinoma	Extremely rare in children	Wide local excision, consider possible higher rate of lymph node spread than in adult
Carcinoma ex pleomorphic	Extremely rare in children	Wide local excision with facial nerve preservation if possible

reported to be 92% (28). The sensitivity of determining that the tumor is malignant is between 84% and 88%, whereas the specificity of malignancy is between 95% and 100%. Reports of performing FNA in children are encouraging, citing minimal discomfort and no need for general anesthesia (28). Unlike certain cases after open biopsies of malignant neck lesions, performing an FNA confers no risk of tumor seeding and does not potentiate difficulties in subsequent resection, tumor fungation through the skin, and early recurrent tumor in the wound (29).

Therefore, the accepted recommendation is for primary FNA for cytologic verification and classification. In cases in which the aspiration biopsy is inconclusive, the minimal procedure for diagnosis and treatment of a solitary mass should be a superficial parotidectomy (or submandibular gland excision) with facial nerve preservation. Because high-grade malignancies are extremely uncommon in children, preservation of the facial nerve should be the rule unless it is involved with the tumor. With this in mind, the parents should always be counseled regarding the risk of facial nerve injury and the need for sacrifice in the event that the intraoperative findings suggest a high-grade malignancy.

Benign Epithelial Tumors

Benign salivary neoplasms of epithelial origin include the pleomorphic (mixed) adenoma, Warthin tumor, oncocytoma, and adenoma (see Table 98.2). The benign mixed tumor is the most common solid tumor mass seen in children (19). Pleomorphic adenomas comprise a heterogeneous mix of epithelial and connective tissue components that are well encapsulated with occasional interdigitation into surrounding parenchyma. The lesions are slow growing, painless, freely mobile, and do not involve the facial nerve. The most common sites of origin are the tail of the parotid and the hard palate.

The imaging of a benign mixed tumor shows the characteristic appearance of a benign mass. On CT scans, the margins are well defined, and the mass is nonenhancing. Larger tumors tend to lobulate, rendering a characteristic appearance on both CT and MRI. On CT, the lobulation appears to be a conglomerate of masses, whereas the finding on MRI confirms a single mass. Calcifications within the mass are highly characteristic of this tumor.

The Warthin tumor (papillary cystadenoma lymphomatosum) is the next most common benign tumor of the major salivary glands and is found only in the parotid gland (26). Its most common manifestation is a unilateral, multifocal, painless mass that quite often is cystic. Histologically, these tumors consist of a double layer of mitochondria-rich oncocytes that rest on a dense lymphoid stroma lining the papillary projections. On CT and MRI, Warthin tumors are well-encapsulated, homogeneous cystic or solid lesions, often in the tail of the parotid. When multiple lesions are seen either in one parotid gland or bilaterally, the most likely diagnosis is a papillary cystadenoma lymphomatosum. Management is superficial

parotidectomy with facial nerve preservation. Oncocytoma (oxyphilic adenoma) describes a solid tumor that is entirely composed of mitochondria-rich oncocytes. The imaging characteristics are nonspecific, and treatment is surgical excision. Monomorphic adenomas occur rarely. They are benign, slow-growing, encapsulated lesions of the parotid gland (in the majority of cases) with occasional minor salivary gland involvement (upper lip) (27). Histologically, these tumors resemble the adenoid cystic carcinoma but lack the invasion seen in the latter. Treatment is surgical extirpation. Other rare benign neoplasms include neurofibromas, xanthomas, and angiolipomas.

Malignant Epithelial Tumors

Cancers of epithelial origin are common in the adult population; however, pediatric epithelial malignancies are rare. A 1972 review by the Armed Forces Institute of Pathology of 9,993 cases of salivary gland lesions demonstrated 430 (4.3%) lesions occurring in children younger than 15 years. Of these, 3% were malignant. Primary malignancies of the salivary gland include carcinomas, sarcomas, and lymphomas. As in the adult population, the most common malignant tumor is the mucoepidermoid carcinoma (MEC). Other less common malignant epithelial neoplasms include the acinic cell carcinoma (16.8% of malignant salivary gland tumors [24]), adenocarcinoma (8.1%), undifferentiated carcinoma (8.7%), adenoid cystic carcinoma (7.6%), squamous cell carcinoma (1.3%), and carcinoma ex pleomorphic. The most common site of malignant salivary gland tumors is the parotid. In general, malignancies of the salivary glands occur later in childhood, whereas the high-grade malignancies are more predominant in the young child (15 years and younger).

MEC is the most common malignant salivary gland tumor in the pediatric population (46% to 55%) (18,24,30). It is a unique epithelial neoplasm composed of variable proportions of epidermoid, mucous, and intermediate cells. Historically, the clinical behavior of this neoplasm is dependent on its histopathologic appearance; ranging from the low-grade benign-behaving type to an extremely aggressive, high-grade neoplasm with a high mortality rate. The low-grade MECs have a high mucinous content, forming cystic spaces. Conversely, high-grade carcinomas are poorly circumscribed, tend to be solid, and have a predominantly squamous composition. Nuclear pleomorphism, high mitotic rate, and necrosis are seen in the high-grade MEC. The intermediate MECs are less cystic and more solid than the low-grade lesions and do not exhibit the features of high-grade neoplasia previously mentioned.

It has been reported that the majority of MECs appear in major salivary glands, and the rest in the minor salivary glands (17,18). MEC is the most common radiation-induced salivary gland malignancy. A greater percentage of salivary gland malignancies appear as second malignancies after radiation (6%) than as primary salivary gland malignancies (0.08%) in children (18). This emphasizes the importance of long-term follow-up of the salivary glands of children who received multimodality therapy for a variety of pediatric primary tumors. The CT and MRI findings vary with the grade of the tumor. The low-grade MEC appears like a pleomorphic adenoma, whereas the high-grade lesions have indistinct infiltrating margins and are more homogeneous.

Treatment of the salivary gland neoplasms includes total parotidectomy with preservation of the facial nerve. Because high-grade malignancies are uncommon in children, facial nerve preservation is the rule if it is not involved with the tumor (17,19) (see Table 89.3). The indications for elective neck dissection are not defined in the literature, but according to some reports, it does not seem to be necessary in children with salivary gland malignancies (17). In patients with clinically suggestive lymphadenopathy, a modified neck dissection is advocated.

The issue of administration of postoperative radiation therapy in the pediatric population is controversial, in light of the inherent risk of developing a second malignancy. Complications related to radiation therapy are not trivial, with one study reporting a 60% rate of sequelae such as dental caries, prolonged trismus, facial deformity, and osteoradionecrosis. Because of the relative infrequency of pediatric salivary gland malignancies, no established and standardized protocols exist for postoperative radiation or chemotherapy. Some authors advocate postoperative radiation therapy for high-grade malignancy, microscopic residual tumor, perineural invasion, soft tissue extension, or multiple levels of lymphadenopathy; presence of a deep tumor with facial nerve involvement; and after salvage surgery (17).

Few clinical reports are found in the literature with respect to adjuvant chemotherapy for malignant salivary neoplasms. Effective regimens include methotrexate and doxorubicin for MEC and a combination of 5-fluorouracil, doxorubicin, and cyclophosphamide (Cytoxan) for treatment of adenocarcinomas and acinic cell carcinoma. Adenoid cystic carcinoma is reportedly best treated with cisplatin, doxorubicin, and 5-fluorouracil (17) (see Table 98.3).

The prognosis of malignant salivary neoplasms in the pediatric population is dependent on the type and grade of tumor. In the MEC, relapse rates for the high-grade malignancies are relatively high but the overall prognosis is good. A recent study from MD Anderson Cancer Center examined 61 patients with salivary gland malignancies. The overall 5-year survival was 93% and 26% developed a recurrence. Seventeen percent had metastatic disease. High tumor grade, positive surgical margins, and perineural invasion were associated with poorer prognosis and increased rates of locoregional recurrence. Of note, late locoregional recurrence was common with the median age of presentation of recurrence of 8 years. This underscores the need for lifelong surveillance of these patients. Furthermore, several patients developed second primary tumors after irradiation, emphasizing the need for vigilance. Patients had lower incidence of late complications compared to adults (30). Another study from the same institution looked specifically

at 49 children with MEC. 5-year and 10-year survival was 98% and 94%, respectively, and 10% of patients had recurrence (31). Cervical lymph node metastasis occurs in 20% to 37% of cases of MECs. Taken together, current data support aggressive treatment of these tumors with long-term follow-up surveillance (24,30).

AUTOIMMUNE CONDITIONS

Sjögren Syndrome

Sjögren syndrome (SS) is an autoimmune condition characterized by chronic inflammation of the salivary and lacrimal glands, resulting in xerostomia and keratoconjunctivitis sicca, respectively. SS may occur alone (primary SS) or in association with other systemic connective tissue disorders such as rheumatoid arthritis, systemic lupus erythematous, scleroderma, polyarteritis nodosa, or dermatomyositis (secondary SS). The common manifestations of salivary gland involvement include bilateral, symmetrical enlargement of the parotid glands (and occasionally submandibular glands). Occasionally, episodes of unilateral or intermittent parotid enlargement can be observed (32).

In children, unlike in the adult population, this condition is uncommon. Nearly 200 cases have been reported in the pediatric population (32). The differential diagnosis for chronic salivary gland enlargement includes primary tumors, lymphoma, acute bacterial and viral infections, sarcoidosis, tuberculosis, histoplasmosis, lead or copper sensitivity, chronic sialadenitis, liver cirrhosis, diabetes mellitus, and malnutrition.

Pediatric SS is a clinical diagnosis based on findings from physical examination, clinical history, and laboratory data, with histologic findings of lymphocytic or plasmacytic infiltration of the involved glands helping to confirm the suspected diagnosis (32). Clinical suspicion should be raised when a constellation of symptoms includes recurrent salivary gland enlargement, chronic xerostomia, or xerophthalmia (33). The evaluation should include Schirmer testing, rose bengal corneal staining with a slit-lamp examination, laboratory evaluation, scintigraphy, and salivary gland biopsy.

The laboratory panel should include erythrocyte sedimentation rate, antinuclear antibody, rheumatoid factor, a complete blood cell count, lupus inhibitor, anti-SS-A/anti-SS-B antibodies, EBV, and quantitative immunoglobulin studies (32,33). These are done to rule out secondary SS. Scintigraphy can be performed to evaluate the functional status of the glands.

A biopsy of the salivary glands should be performed to confirm the suspicion of SS. Minor salivary gland biopsy has become widely used as the diagnostic modality of choice. However, lip biopsies have been shown to be poorly sensitive and often provide inadequate salivary gland samples. Reports in the literature cite a rate of sensitivity of 33% to 58% by using lower-lip biopsy (32). In one of the more recent publications, McGuirt et al. (32) performed biopsies of the tail of the parotid and showed a 100% sensitivity rate in six patients. No complications were reported with this type of biopsy, but it does produce a cutaneous scar. Histopathologically, SS is identical to what has been known as Mikulicz disease.

Treatment is directed at prevention of intraoral and ocular complications due to the sicca syndrome. Chronic xerostomia increases the incidence of dental caries; appropriate methods of prevention of dental caries include reduction of sugar intake, topical fluoride application, and close monitoring of dental plaque. Symptoms of severe xerostomia can be alleviated by frequent mouth rinses with water, over-the-counter artificial saliva, aerosolized water/glycerin combinations, and use of sialogogues. More recently, pharmaceutical agents such as pilocarpine (Salagen) have been recommended for treatment of adult xerostomia. Unfortunately, no studies have been performed in the pediatric population to prove safety and efficacy.

In cases of primary SS, long-term follow-up is necessary to ensure that no systemic disease has developed. In cases of secondary SS, treatment with systemic antiinflammatory agents is necessary. In the short term, systemic antibiotics and corticosteroids are necessary to manage symptomatic parotid swelling (see Table 89.1). Another reason for long-term follow-up of these patients is the occasional association of SS with lymphoma in the adult population. Numerous reports document the increased risk of non-Hodgkin lymphoma 6 months to 13 years after the initial diagnosis of SS in adults. With this in mind, among the 200 reported cases of SS in the pediatric population, lymphoma has developed in none (32,33).

OTHER DISORDERS

Sialorrhea

Excess drooling, or sialorrhea, is the pathologic loss of saliva from the oral cavity. It is most commonly seen in the neurologically or mentally impaired patients. It is an important clinical problem in about 10% to 38% of patients with cerebral palsy (CP) (34).

Drooling is a normal physiologic condition seen in the infant until maturation and social awareness are achieved. Commonly, by age 3 to 4 years, drooling should resolve. Approximately 1.5 to 2 L of saliva per day is produced in the oral cavity and oropharynx. In the nonstimulated state, nearly 80% of the flow is produced by the submandibular glands and the sublingual glands, 10% to 15% by the parotid glands, and 5% to 10% by the minor salivary glands (35,36). Sialorrhea is often a manifestation of a discoordinated swallowing mechanism, most commonly in the oral phase. This deficit may be central, as in CP or mental retardation, or peripheral, as in facial nerve or glossopharyngeal nerve palsy (36). It is not due to an overproduction of saliva, as studies have shown that drooling patients

produce the same amount of saliva as do controls (37). A number of other factors contributing to sialorrhea include poor head control, constant open-mouth posture, poor lip and tongue control, hypoactive gag reflex, diminished intraoral sensation, and constant tongue-thrusting movement. Drooling also can be due to chronic nasal obstruction secondary to adenotonsillar hypertrophy, nasal septal deformity, turbinate hypertrophy, or rhinorrhea. Nasal obstruction may exacerbate sialorrhea by encouraging an open-mouth position. These potential sites of pathology should be addressed before manipulation of salivary flow.

The management and evaluation of sialorrhea should be interdisciplinary, and important issues to consider are dental disease, head positioning, malocclusion, airway obstruction, and the side effects of medical therapy.

The initial treatment of sialorrhea is noninvasive. This approach includes physiotherapy, anticholinergic/antihistamine pharmacotherapy, or both. Physiotherapy has been shown to be effective in higher-functioning children but is effective as an adjunct even in children with less neuromuscular coordination if started early in infancy (36). Even though the results are not overwhelming, it is recommended to undergo a physical therapy consultation before surgical intervention (36) (see Table 98.1).

Depending on the modality of therapy chosen, the treatment of drooling may lead to problems with oral health. Saliva buffers and provides ions for remineralization of the teeth, and so regular dental exams are important to encourage in order to minimize carries and other pathologies such as gingivitis, tooth destruction, cheilitis, crusting of the tongue/palate, and burning sensation intraorally (38).

The aim of pharmacotherapy is to reduce salivary flow by blocking parasympathetic stimulation of the salivary glands. The lack of compliance and success with this route of treatment stems from intolerable side effects such as urinary retention, constipation, blurred vision, xerostomia, and restlessness, making these drugs less desirable for long-term use. The results with oral medications are not consistent and dose dependent and must be used with caution in patients with cardiac disease, pyloric obstruction, ileus, etc.

Radiation therapy for management of sialorrhea is no longer recommended because of the risk of developing a malignancy.

Multiple different surgical options exist for patients with excessive drooling. Surgical management of drooling has been directed at either rerouting the flow of saliva or reducing the salivary output. The goal is to reduce salivary flow significantly while maintaining a moist intraoral environment to avoid dental caries and xerostomia. Submandibular duct rerouting was previously commonly used. The procedure is easy to perform and has reportedly good results; however, the increase in salivary flow to the oropharynx may cause salivary contamination of the lower respiratory tract. Rerouting in a patient with severe spastic esophageal disease or esophageal stricture should be avoided, and a barium swallow is an indicated preoperative study. Complications related to submandibular duct relocation include ranula and lateral neck cyst formation, requiring additional surgery. Some institutions recommend addition of simultaneous sublingual gland excision to complete the procedure (39). In performing this procedure, it is crucial to avoid the large veins in the floor of the mouth as ligation of those veins may result in tongue edema.

Denervation of the parasympathetic stimulus via bilateral tympanic neurectomy or bilateral chorda tympani nerve section has a reported success rate ranging from 47% to 100%. For an approximate success rate of 75%, both nerves must be sectioned bilaterally (40). Disadvantages include short-term success due to late regrowth of preganglionic fibers, loss of taste to the anterior two-thirds of the tongue, production of mucoid saliva, and bilateral otologic procedures. The main contraindication is a history of unilateral sensorineural hearing loss.

Submandibular gland excision also is an option, either alone or in combination with another procedure. The approach to this gland is simple and familiar to the otolaryngologist. Obviously, salivary flow is significantly diminished, potentially promoting dental caries and dysphagia secondary to lack of lubrication. Excision of the parotid glands has not been advocated because of risk of injury to the facial nerves.

Parotid duct ligation is commonly performed in conjunction with submandibular duct excision to control sialorrhea. Ligation of the submandibular ducts is not recommended because of the increased risk of calculus formation in comparison with the parotid. This is hypothesized to be due to the higher alkalinity and viscosity of submandibular saliva, the higher concentration of calcium and phosphate salts, the longer duct system, and the stasis that is associated with the orifice being superior to the gland (41).

At our institution, the recommended approach is bilateral submandibular gland excision with bilateral parotid duct ligation. This targets the resting salivary gland flow as well as the stimulatable salivary production during food intake. A review of 93 patients undergoing this procedure showed a significant improvement in drooling in 65% of patients and elimination of drooling in 21% of the patients (41). Another study of 33 patients examined patient caregiver satisfaction after various surgical interventions. Patients undergoing four duct ligations had markedly lower satisfaction scores and higher recurrence rates when compared to submandibular gland rerouting with sublingual gland excision and submandibular gland excision with parotid duct ligation (42). A recent metaanalysis found overall surgical success to be 81.6% across all studies. The highest rate of success was with bilateral submandibular gland excision and parotid duct rerouting, with rates that were similar to those for submandibular gland excision with parotid duct ligation (43,44).

Recent reports suggested using botulinum neurotoxin type A injections into the major salivary glands as an option for management of sialorrhea. The therapeutic effect is based on the anticholinergic action of the toxin at the level of the salivary gland receptors. Thus, injection

of botulinum toxin can depress the secretory capacity of the glands, which is responsible for secretion of water and electrolytes. It has been shown, too, that the toxin does not affect the adrenergic portion of salivary gland innervation, which is mainly responsible for protein discharge. Thus, the patient retains a sufficient basal secretion, avoiding xerostomia and dental caries. The intraglandular injections should be performed with a 25-gauge needle with ultrasound guidance. According to the protocol reported by Jongerius et al. (34), weight-dependent dosages are injected into each gland: 15 U/gland for children who weigh less than 15 kg, 20 U/gland for children weighing between 15 and 25 kg, and 25 U/gland for children who weigh more than 25 kg. Each dose is fractionated and divided over three sites in the gland. This study also suggested a similar efficacy between the use of Botox and scopolamine, yet without the side effects of the medical form of management.

A recent study by Khan et al. of 45 children injected with Botox for sialorrhea showed that 80% of caregivers reported increases in quality of life associated with decreased drooling. Mean duration of effect was 4.6 months. Side effects were generally mild, but did include several cases of dysphagia and one episode of aspiration pneumonia (45).

Botox B has been used for management of dystonia; however, due to immunogenic effects (by creating autoantibodies) and due to higher autonomic side effects, it is not frequently used for this indication (46).

When persistent or recurrent sialorrhea is observed after surgical intervention, radionuclide scans using a 99m technetium pertechnetate (^{99m}Tc) might be useful in elucidating the need for repeated ligation of the parotid ducts. However, no well-designed studies have reported findings in groups of patients who underwent successful procedures compared with those with poor results to allow useful interpretation of these scans (39).

Trauma

Injury to the salivary glands can be the result of blunt and penetrating trauma as well as secondary to radiation therapy. A systematic evaluation of gland parenchyma, duct integrity, and facial nerve status will ensure proper management. Injury to the gland's substance does not require specific therapy, except for wound irrigation and possible drainage and antibiotics. Facial nerve function evaluation is essential on presentation. Deep penetrating wounds with facial nerve compromise should be surgically managed within 3 days. Injury anterior to Ohngren line (an imaginary vertical line between the lateral canthus and mental foramen) does not require repair of the facial nerve, as regeneration is highly likely. Posterior to this line, primary repair is required. Exploration of the main trunk of the facial nerve and identification of its branches will help identify proximal and distal nerve stumps.

When a penetrating wound is found posterior to the anterior border of the masseter, injury to Stensen's duct should be suspected. This requires wound exploration and primary repair, most often over an inert silicone rubber (Silastic) stent. Probing the duct transorally should help in identifying the site of injury if it is not clearly seen on wound exploration. If primary reanastomosis is not possible because of loss of duct substance, then the duct can be rerouted intraorally. Another option is to ligate the proximal stump, allowing the parotid gland to atrophy. Salivary gland hematomas or pseudocysts may result from blunt trauma. Historic details will usually elucidate the etiology of an acute onset of a parotid mass as a hematoma or a delayed presentation of a cyst. It may be necessary to aspirate or drain these collections. A pressure dressing should be applied to avoid reaccumulation of the fluid. Pretreatment ultrasonography will usually be diagnostic.

Much less common in the pediatric population is the occurrence of pneumoparotitis, which requires no treatment. This is seen in individuals who require increased intraoral/buccal pressure to play a musical instrument or in glassblowers.

The salivary glands are sensitive to radiation trauma. Xerostomia is an expected complication and can be managed with artificial saliva preparations. Increased hydration and use of sialogogues should be encouraged to avoid dental caries. Close surveillance is important as well, as the risk of a secondary malignancy is increased even after low-dose radiation.

HIGHLIGHTS

- The most common pediatric salivary gland disorders are inflammatory.
- All pediatric salivary gland cysts should be evaluated to exclude HIV as an underlying etiology.
- Sialolithiasis is uncommon in the pediatric population. The most commonly affected site is the submandibular gland, followed by the parotid. Ninety percent of the calculi are radiopaque.
- Salivary gland neoplasms represent 8% of pediatric head and neck neoplasms (fourth most common after nasopharyngeal, skin, and thyroid tumors).
- Fifty percent of pediatric salivary neoplasms, excluding vascular neoplasms, are malignant (higher rate than in adults). A solid mass in a child is 2.5 times more likely to be malignant than it is in the adult.
- Seventy-four percent of benign salivary tumors are hemangiomas. The majority occurs in the parotid gland, and diagnosis is clinical. Treatment is conservative unless rapid progression or functional obstruction occurs.
- Lymphangiomas account for 19% of benign salivary neoplasms in the pediatric population. Unlike hemangiomas, lymphangiomas do not replace the glandular parenchyma. Treatment is surgical.

- The parotid gland is the predominant location for salivary tumors (65.8%). The majority of these tumors are malignant (80%) and appear at the angle of the mandible.
- A role for FNA exists in diagnosing salivary gland tumors; however, definitive diagnosis should be based on permanent pathology sections.
- Although the CT scan is the diagnostic modality of choice for evaluating salivary gland diseases, the jury is out with respect to CT versus the use of MRI.

Otitis Media in the Age of Antimicrobial Resistance

99

Margaretha L. Casselbrant *Ellen M. Mandel*

Otitis media (OM), inflammation of the middle ear, is, next to the common cold, the most common diagnosis made in children. Prior to the antibiotic era, it was a very serious disease with high morbidity and mortality due to intratemporal and intracranial complications. With the introduction of antibiotics, the frequency of sequelae and complications were reduced. However, overuse of antibiotics in the treatment of acute otitis media (AOM) and otitis media with effusion (OME) has led to the development of resistant bacteria. Therefore, judicious use of antibiotics is recommended, and today, watchful waiting without antibiotics may be considered as an option in mild disease, especially in older children.

DIAGNOSIS

Definition/Symptoms and Signs

Although considered to be a continuum, OM can be subclassified into AOM and OME based on signs and symptoms. As the treatment of AOM and OME differs, it is important to accurately diagnose the two conditions. AOM is generally characterized by rapid onset of signs and symptoms of inflammation in the middle ear accompanied by middle-ear effusion (MEE). Signs of inflammation include bulging or fullness of the tympanic membrane (TM), erythema of the TM, and acute perforation of the TM with otorrhea. Symptoms include otalgia, irritability, and fever. OME, on the other hand, is defined as MEE without signs and symptoms of acute inflammation as found in AOM (Fig. 99.1).

Pneumatic Otoscopy

Pneumatic otoscopy is the primary diagnostic tool to evaluate the status of the middle ear as it allows for assessment of the TM and its mobility. The normal TM is translucent, concave, and moves briskly with application of positive and negative pressure. A visible landmark is the handle (manubrium) of the malleus, which is attached to the TM, with the umbo in the center of the TM. To adequately visualize the TM, the external ear canal must be cleared of cerumen and debris. The assessment of the TM should include *position, color, degree of translucency, and mobility*. To ascertain the mobility of the TM, a good airtight seal must be obtained between the speculum and the ear canal. The largest speculum that fits comfortably should be used. A bulb through which air is puffed should be attached to the otoscope, allowing for visualization of TM mobility. Reduced or no mobility of the TM indicates loss of compliance of the TM either as a result of effusion in the middle ear or increased stiffness due to scarring or increased thickness of the TM. Total absence of mobility of the TM may also be due to an opening in the TM either as a perforation or a patent tympanostomy tube. Other features, such as fluid levels or bubbles, may be more easily discerned with movement of the TM. The position of the TM ranges from severely retracted to bulging. Mild to moderate retraction indicates negative pressure, MEE, or both, while a severely retracted TM is usually associated with effusion. Fullness and bulging of the TM is caused by increased pressure, fluid, or both, in the middle ear. Opacification of the TM may be caused by thickening or scarring or middle-ear effusion. A red but translucent TM is usually caused by crying or sneezing due to engorgement of blood vessels in the TM. On the other hand, a "red" opaque TM that is full or bulging is often a sign of AOM. A pink, gray, yellow, or blue retracted TM with reduced or no mobility is usually seen with OME. Myringitis is inflammation of the TM without fluid in the middle ear. Use of an *operating microscope (otomicroscopy)* may clarify features seen on otoscopy, and visualization of scarring and atrophy of the TM may be enhanced. Use of a Siegel otoscope with the otomicroscope to provide the pneumatic component is advised.

Immittance Testing (Tympanometry)

Immittance testing (tympanometry) is an excellent adjunct to the assessment of middle-ear status and the management of OM. When otoscopic evaluation is uncertain or difficult to perform, tympanometry can be very useful in evaluating ear disease in children. It is easy to perform and most often well accepted by the patient. It has been used for school screening as well as in pediatricians' offices. It is also valuable for documentation of middle-ear status over time with repeat testing. The most commonly used frequency for tympanometric testing is 226 Hz; however, for children less than 6 months of age, a frequency of 1,000 Hz is recommended. A small probe that emits a tone is placed in the ear canal with an airtight seal. The tympanogram is obtained by plotting the immittance (acoustic energy of the reflected tone) of the middle ear as a function of the pressure in the external ear canal, which is varied from −400 to +200 daPa. The instrument provides measures such as peak compensated (static) admittance, tympanometric peak pressure, acoustic reflex, and tympanometric width (TW), a measure of gradient. Algorithms have been developed to determine the presence or absence of MEE, some combining pneumatic otoscopy and tympanometry. The following set of criteria using TW to categorize middle-ear status is used: TW < 150 daPa = no OME, TW > 350 daPa = OME, and TW between 150 and 350 daPa = presence or absence of OME is determined by otoscopy (1). A flat or rounded pattern (TW > 350 daPa) with a small ear canal volume indicates MEE, while a flat pattern with a large ear canal volume suggests a perforation or a patent tympanostomy tube. In a normal air-filled middle ear with equal pressure on both sides of the TM, the peak pressure of the tympanogram is 0 daPa. Other methods of ascertaining middle-ear status have been investigated including spectral gradient acoustic reflectometry (2,3) and ultrasound (4), but they have been found to have limitations, although they may be useful for screening.

Audiometry

MEE usually results in a mild to moderate conductive hearing loss. The assessment of hearing is essential to management, as hearing impairment can predispose to delay in speech and language development and may later affect school performance. Audiometry should be used to help

determine management of the child, with more aggressive management considered if there is significant hearing impairment.

Behavioral audiometry requires cooperation of the child with the examination, and the test is adapted to the age of the child. *Visual reinforcement audiometry* is used for children 6 months to 2 years of age and involves presentation of a sound stimulus in the sound field with observation of the child's conditioned head turn response. This is rewarded with a visual reinforcement such as an animated toy. *Play audiometry*, for children older than 2 years, is similar to *conventional audiometry* (for children over 5 years of age), but the child places toys in a bucket rather than raising a hand to acknowledge they heard the sound. *Conventional* hearing thresholds in the sound field or ear-specific are determined at 0.25, 0.5, 1, 2, 4, and 8 kHz, depending on the age of the child. High frequency testing, from 12 to 20 kHz, can also be obtained in children (see Chapter 100).

Auditory brainstem audiometry (ABR) and *transitory otoacoustic emission (TOAE)* are excellent methods for testing children who do not cooperate with behavioral hearing evaluation because of very young age or developmental delay. Except for infants, sedation or general anesthesia is usually necessary for ABR testing in younger children. Three electrodes are placed (forehead and each mastoid process) to record the response to clicks of 2,000 to 4,000 Hz or pure-tone burst. The ABR consists of five to seven vertex positive waves. Waves I to III presumably reflect activity of the auditory centers in the eighth nerve fibers and pons; waves IV and V presumably reflect activity of the auditory centers in mid- to rostral pons and caudal midbrain, respectively; and activity from waves VI and VII is less certain. The ABR reflects auditory neural electrical responses that are adequately correlated to behavioral hearing thresholds. However, a normal response on the ABR suggests only that the auditory system up to the midbrain level is responsive to the stimulus employed. Thus, it does not guarantee normal hearing.

Transitory otoacoustic emissions measure cochlear function (outer hair cells) and is an objective test of auditory function. It is commonly used for newborn hearing screening as it is fast and easy to perform. It is excellent for testing children who do not cooperate with behavioral testing. MEE may confound the results. Therefore, if the OAEs are absent, immittance testing should be performed to assess the middle ear. For children who fail TOAE testing, follow-up audiologic testing must be done to assess type and degree of hearing loss.

EPIDEMIOLOGY

Incidence and Prevalence

OM is considered a worldwide pediatric health care problem. The Early Childhood Longitudinal Study-Birth Cohort (ECLS-B), a nationally representative longitudinal study of more than 8,000 children born in 2001, showed that OM was diagnosed in 39% of children by 9 months and 62% of children by 2 years of age (5). Although the highest incidence of OM is in young children, it occurs in older children, adolescents, and adults. The Oslo Birth Cohort, enrolling infants born in 1992 to 1993, found that among 10-year-olds 13% had at least one episode of OM in the previous 12 months (6). Approximately 3% to 15% of patients with OM referred to otolaryngology clinics are adults (7). While recent studies from the United States (8), Norway (9), the Netherlands (10), and the United Kingdom (11) have indicated that there is a general decline in OM incidence, studies from developing countries and indigenous populations continue to demonstrate a heavy burden of OM (12,13).

Acute Otitis Media

Most children experience at least one episode of AOM during their childhood. The cumulative incidence of the first episode of AOM based on studies from various countries ranges from 19% to 62% by age 1 year and 50% to 84% by 3 years of age (Fig. 99.2) (14–20). In the majority of these studies, the peak incidence of AOM occurred during 6 to 12 months of life (20). The incidence decreases with age, and by 7 years of age, few children experience episodes of AOM. Recurrent episodes of AOM are common in young children. By 6 months of age, 20% have had two or more episodes (21). Three or more episodes of AOM by ages 1, 3, 5, and 7 years have been documented in 10% to 19%, 50%, 65%, and 75% of children, respectively (20). Six or more episodes of AOM were documented in 39% of children by age of 7 years. It should be noted that these data were obtained prior to the use of pneumococcal vaccine in infants and young children.

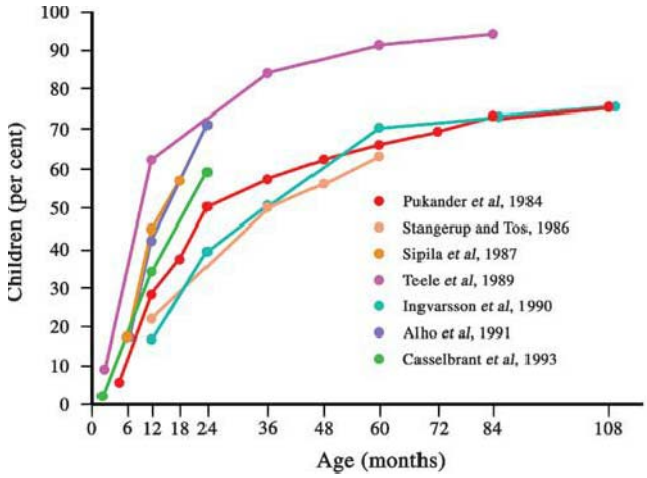

Figure 99.2 Cumulative incidence of first episode of AOM. (Reproduced from Casselbrant ML, Mandel EM. Epidemiology. In: Rosenfeld RM, Bluestone CD, eds. *Evidence-based otitis media*, 2nd ed. Hamilton, ON: BC Decker, 2003:147.)

Otitis Media with Effusion

It may be difficult to determine the "true" incidence of OME as by definition OME is asymptomatic. Therefore, a short time between observations is needed to precisely assess the onset and time to resolution of each new episode of OME as approximately 65% of OME episodes in children 2 to 7 years resolve within 1 month (22). Monthly examinations with otoscopy and tympanometry in 2- to 6-year-old children in a day care center in Pittsburgh revealed MEE at least once in 53% to 61% of the children and a Danish study found an incidence of MEE of 26% in 7-year-old children followed monthly for 1 year using tympanometry (23).

The point prevalence of MEE from different countries shows a wide variation depending on the age of the child, season of the year, as well as type of assessment. Thus, it must be emphasized that when comparing the outcome between studies, there is a need to evaluate study methodology and exercise caution when drawing conclusions. However, nearly all children experience at least one episode by 3 years of age (24).

Risk Factors

Risk factors can be host related (age, gender, race, prematurity, allergy, immunocompetence, cleft palate and craniofacial abnormalities, genetic predisposition) as well as environmental (upper respiratory infections [URIs], seasonality, day care, siblings, tobacco smoke exposure, breast-feeding, socioeconomic status, pacifier use, and obesity) and are considered important in the occurrence, recurrence, and persistence of middle-ear disease.

Host-Related Factors

Age

The highest incidence of AOM occurs between 6 and 11 months of age (20), and onset of the first episode of AOM before 6 months (20) or 12 months of age is a powerful predictor of recurrence (25). The risk of persistent MEE after an episode of AOM is inversely correlated with age (20), and children who experience their first episode of MEE before 2 months of age are at a higher risk for persistent fluid during their first year of life than are children having their first episode later (26).

Sex

Most investigators have reported no apparent sex-based difference in the incidence of OME. Some studies have found a significantly higher incidence of AOM in males as well as more recurrent episodes than in females, but others have not found this (24).

Race

Previous studies have suggested a lower incidence of OM in black children compared to white children. However, more recent studies in which the children were followed prospectively with examinations of the ears every 6 weeks showed no difference between the black and white children in their experience with OM (27,28). One study, part of an American population–based sample survey evaluating school children ages 6 to 10 years with tympanometry, also reported no difference between black and white children. However, the prevalence of OME was significantly higher in Hispanic children compared to white children (29).

Allergy/Immunocompetence

Controversy remains regarding the role of allergy in the pathogenesis of OM as allergy is a common problem in children, occurring at a time when respiratory infections and OM are common. Most, but not all, of the epidemiologic studies have supported an association. Pukander and Karma (30) found, in 707 children with AOM, that in children with atopic manifestations, the persistence of MEE for 2 months or longer was greater than in children without allergy. However, in another study, atopic diathesis was not found to predispose a child to the development of AOM (31). Tomonaga et al. (32) determined that allergic rhinitis was present in 50% of 259 patients (mean age of 6 years) in whom OME had been diagnosed while OME was present in 21% of 605 patients (mean age of 9 years) in whom allergic rhinitis had been diagnosed. Among 108 children (ages 5 to 8 years, mean age of 6 years) in whom neither condition had been diagnosed, the incidences of allergic rhinitis, OME, and both of these conditions were 17%, 6%, and 2%, respectively. Another investigative group (33) compared 76 children with MEE admitted for bilateral myringotomy with tube insertion (M&T) to 76 controls matched by age, gender, and season of admission for a general surgical procedure. Results showed a nearly fourfold increase in the risk of persistent MEE in children who had atopic symptoms for more than 15 days per month. In another study, Bernstein and Reisman (34) determined the allergy status of a group of 200 children who had undergone one or more M&T procedures. They diagnosed allergy in 23% of the entire group but found that the frequency was 35% among the 88 children with multiple myringotomies with tube insertions. The frequency of allergy in these patients was higher than that reported for children of similar age in the general population. The above studies generally found a higher frequency of OME in allergic children compared with age-matched nonallergic children, as well as higher frequencies of allergy in children with OME compared with children without OME. Skoner et al. (35) suggested that if significant allergic rhinitis is diagnosed in a patient with OME, it should be treated aggressively. More studies are needed to evaluate the relationship between these two conditions.

Children with recurrent OM as well as other recurrent infections may have a defect in the immune system such as a defect in phagocyte function, humoral immunity, local

immunity, or other immune defects (36). Immunologic screening is indicated to exclude an immunodeficiency in children with frequent episodes of OM or an abnormal course of disease (37). While agammaglobulinemia and hypogammaglobulinemia are rare, deficient or lowered immunoglobulin (Ig)A or decreased levels of one or more IgG subclasses, in particular IgG2, are more common. The specific antibody response to bacterial capsular polysaccharides is often low. Kaur et al. (38) reported finding that, after an episode of AOM due to *Streptococcus pneumoniae*, otitis-prone children and children who failed treatment for AOM had less of an IgG serum antibody response compared to non-otitis-prone children to proteins of *S. pneumoniae*. Children infected with the human immunodeficiency virus have a significantly higher recurrence rate than normal children or children who have seroconverted (39).

Cleft Palate/Craniofacial Abnormality

To date, no evidence suggests an effect of cleft palate/cleft lip type or laterality on OME prevalence (40), and an equally high OME prevalence was reported in patients with diagnosed submucosal cleft palate (41) but not in patients with bifid uvula (42,43). OM is considered "universal" in infants less than 2 years of age with unrepaired cleft palate (44). After surgical repair of the palate, the occurrence of OM is reduced, which is most likely due to improvement of eustachian tube function. In a prospective study of 150 children with cleft lip and palate, enrolled between 2 and 18 months of age, Robinson et al. (45) reported a 92% prevalence of OME before palate repair, no short-term change after palate repair, but a reduced prevalence to 70% at 4 years of age. Many children continue to have problems up into the teens. A reduction of middle-ear disease by newer palatoplasty procedures has been suggested (46). OM is also common in children with other craniofacial abnormalities also due to anatomical or functional eustachian tube dysfunction (47). Down syndrome children have, in addition to poor active eustachian tube function, low resistance of the eustachian tube, which predisposes to reflux of nasal secretions into the middle ear (48).

Genetic Predisposition

The frequency of the occurrence of one episode of OM is so high that a genetic predisposition cannot be expected. However, a predisposition to recurrent episodes of OM and chronic MEE may have a significant genetic component. The etiology of OM is multifactorial, involving environmental as well as genetic factors. A large number of genes may be involved, each contributing to a particular increase in disease risk.

Twin and triplet studies have been used to assess the heritability of OM. Two retrospective studies using questionnaires have been published. The first study, using 2,750 Norwegian twin pairs, estimated the heritability at 0.74 in females and 0.45 in males (49). In the second study, the estimated heritability was, on average, 0.57 at ages 2, 3, and 4 years (50). In a prospective twin/triplet study from Pittsburgh with monthly assessments of middle-ear status, the heritability estimate for OM at age 2 years was 0.79 in females and 0.64 in males (51). Heritability is a population statistic to ascertain if a trait is heritable, while linkage and association studies may identify genetic regions or specific genes influencing the particular trait or disease. Daly et al. (52), using genome-wide linkage analysis, have suggested that regions of chromosomes 19q and 10q contain genes contributing to the susceptibility to chronic OME/recurrent AOM. Subsequent fine mapping of both regions further strengthened the evidence for this linkage (53). A second genome-wide linkage analysis demonstrated linkage regions with plausible candidate genes in 17q12 (AP2B1, CCL5, and a cluster of other CCL genes) and in 10q22.3 (SFTPA2) (54). Polymorphisms in mannose binding proteins (55), surfactant protein (56), mucin expression (57), and cytokines (58,59) have been associated with mucosal immunity and development of disease. In addition, polymorphisms in three genes (FBXIIO, TLR4, and PAII) originally identified in mouse models of OM have shown evidence of susceptibility to childhood OM in cohort studies (60–62).

Environmental Factors

The main risk factors for OM are day care, number of siblings, tobacco smoke exposure, breast-feeding, birth weight, socioeconomic status, and air pollution. Environmental risk factors for OM across Western countries, including European countries, the United States, Canada, and Australia, have shown large variations in rates across the various countries: day care at ages 1 to 3 years (Sweden 75% vs. Italy 6%), breast-fed at 6 months (Norway 80% vs. Poland 6%), and women smoking (Germany, France, and Norway 30% to 40% vs. Portugal less than 10%) (63).

Upper Respiratory Infection/Seasonality

Both epidemiologic evidence and clinical experience strongly suggest that OM is frequently a complication of an URI. The incidence of AOM is highest during the fall and winter months and lowest during spring and summer months, which parallels the incidence of URI (22). This supports the hypothesis that an episode of URI plays an important role in the etiology of OM. Rhinovirus, RSV, adenovirus, and coronavirus have been detected in MEE during episodes of AOM (64,65). Winther et al. (66) reported that the OM complication rate of a cold-like illness was 33%. The predominant virus in this population was the rhinovirus.

Day Care/Home Care/Siblings

Almost universally, day care center attendance remains a very important risk factor for development of OM. For example, prevalence of high negative middle-ear pressure

and flat tympanograms (type B), indicative of MEE, have been shown to be highest in children cared for in day care centers with many children, intermediate in children in family day care with fewer children, and lowest in children cared for at home (67). Data from the United States ECLS-B, including more than 8,000 children studied at 9 months and 2 years of age, showed a significant increased risk for recurrent AOM and tube insertion for children attending day care (5).

Birth order has been shown to be associated with episodes of OM and percentage of time with MEE (22). Firstborn children had a lower rate of episodes of AOM and less time with MEE during the first two years of life than children with older siblings. Also, having more than one sibling was significantly related to early onset of OM (30), and the presence of more children in the household was related to more time with MEE (28).

The reason for the higher morbidity in children in day care centers and in children with older siblings may be related to the greater opportunity for exposure to viral URI, which may cause eustachian tube dysfunction leading to the development of OM.

Tobacco Smoke Exposure

An association between OM and passive exposure to smoking has been reported by many investigators, while others have not been able to demonstrate such an association. In most studies, the information regarding smoke exposure has been obtained from the parents. A few studies have measured cotinine, a metabolite of nicotine, in blood, urine, or saliva of the child and have been able to more accurately determine the association between OM and smoke exposure (21,68). More information about the pathogenesis, duration, and intensity of exposure is needed to clarify this association. Two studies have shown an association between middle-ear status and parental smoking. In children exposed to parental smoking, tympanostomy tubes stayed in place for 59 weeks compared to 86 weeks in children who were not exposed to smoking (69). Also, myringosclerosis was more prevalent in children with two smoking parents compared to those with no smoking parents (64% vs. 20%), and maternal smoking was associated with a highly increased risk of recurrent OM after insertion of tympanostomy tubes (70).

Breast-/Bottle Feeding

Breast-feeding for 6 months exclusively is recommended by most national and international authorities, including the American Academy of Pediatrics and the American Academy of Family Physicians, the World Health Organization (WHO), and the United Nations Children's Fund. In 2002, Kramer and Kakuma (71) published a comprehensive review of the world literature to determine health benefits of exclusive breast-feeding for 6 months compared to 3 to 4 months. They reported a decrease in the risk for gastrointestinal infection even in developed areas. It had not been shown previously that exclusive breast-feeding for 6 months or longer compared to 4 to less than 6 months in the United States provided greater protections against respiratory infections. Therefore, a secondary analysis of data from the National Health and Nutrition Examination Survey III, a population-based cross-sectional home survey conducted from 1988 to 1994, was undertaken (72). After adjusting for demographic variables, child care and smoke exposure, the data revealed statistically significant increased risk for both pneumonia (OR: 4.27; 95% CI: 1.27 to 14.35) and three or more episodes of OM (OR: 1.95; 95% CI: 1.06 to 3.59) in those children breast-fed 4 to less than 6 months. These findings further support the current recommendations that infants receive breast milk exclusively during the first 6 months of life.

Socioeconomic Status

Socioeconomic status and access to health care are factors that may affect the incidence of OM. It has been generally thought that OM is more common among the lower socioeconomic strata due to poor sanitary conditions and crowding. Paradise et al. (28) followed 2,253 infants for 2 years in the United States and found an inverse relationship between the cumulative proportion of days with MEE and socioeconomic status. However, many studies have not revealed any correlation between socioeconomic status of the child's family and the incidence of MEE.

Pacifier Use

Niemelä et al. (73) reported that pacifier use increased the annual incidence of AOM and calculated that pacifier use was responsible for 25% of AOM episodes in children younger than 3 years. They reported the results of an intervention trial in which parents in various well-baby clinics were taught that pacifier use was harmful and should be limited, while parents in other clinics were not provided with this information. This led to a 29% decrease in AOM in the group provided with pacifier information. Pacifier use has been theorized to contribute to the development of OM, possibly due to the sucking action of the child propelling nasopharyngeal secretions into the middle ear or by the pacifier acting as a fomite. However, Brook and Gober (74) cultured the surface of pacifiers from children with AOM but found no pathogens typical of AOM. The role of pacifier use in AOM remains unclear.

Obesity

Recent studies have indicated that there may be an association between OM and body mass index (BMI). Tympanostomy tube insertion and overweight were studied in a predominantly white cohort of children (97%) followed from birth to 2 years of age (75). Weight for length and BMI

for age were calculated using well-child visit data. A history of tympanostomy tube insertion significantly predicted risk of BMI index at both greater than 95th percentile and greater than 85th percentile at 2 years of age after controlling for risk factors and confounders. However, early weight status was not related to later OM, recurrent OM, or tympanostomy tube insertion. In another cohort of American Indian children, a history of recurrent AOM increased the likelihood of weight-for-length index greater than 95th percentile (76). The mechanisms are not clear, but it was suggested that inflammatory changes in the middle ear can result in objective gustatory changes.

PATHOPHYSIOLOGY AND PATHOGENESIS

The pathophysiology of OM is multifactorial with various overlapping factors (Fig. 99.3).

Eustachian Tube Function

The eustachian tube in the infant is shorter, wider, and more horizontal than in the adult, which leads to the high rate of OM in infants and children. By 7 years of age, when the tube has a more adult configuration, the prevalence of OM is low (77). The three physiologic functions of the eustachian tube are (a) *pressure regulation* (ventilation), (b) *protection*, and (c) *clearance* (drainage). Of these three functions, pressure regulation is the most important (36) (Fig. 99.4). Middle-ear pressure is equilibrated to atmospheric pressure through active intermittent openings of the eustachian tube caused by contraction of the tensor veli palatini muscle during swallowing, jaw movements, or yawning. If active function is impaired, negative pressure will develop in the middle ear. Pressure regulation can be impaired by failure of the opening mechanism *(functional obstruction)* or anatomical *(mechanical)* obstruction. In ears with normal eustachian tube function, the eustachian tube is collapsed when at rest. This protects the middle ear from nasopharyngeal sound pressure and reflux of secretions from the nasopharynx. The clearance of secretions produced within the middle ear into the nasopharynx is provided via the mucociliary system and through the "pumping action" of the eustachian tube during closing. The passive closing of the tube is initiated at the middle-ear end of the eustachian tube and progresses toward the nasopharyngeal end, which results in removal of the secretion.

Using a pressure chamber, Bylander et al. (78) evaluated eustachian tube function in children and adults who were considered otologically normal with intact TMs. While only 5% of the adults were not able to equilibrate negative middle-ear pressure, as many as 35.8% of the children

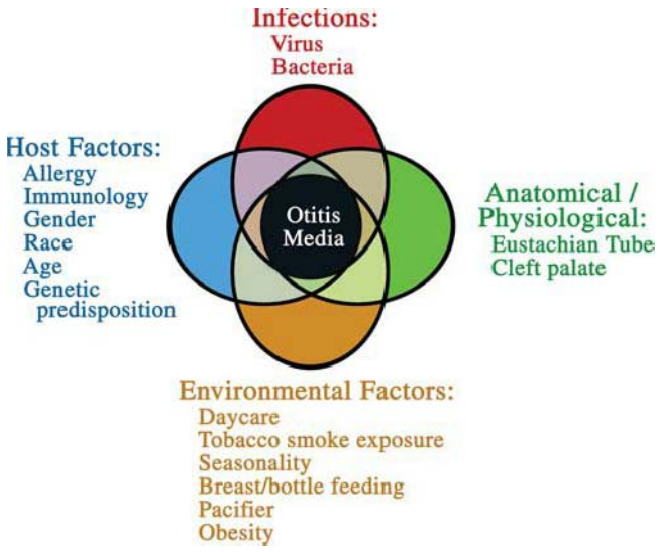

Figure 99.3 Various factors interact in the pathogenesis of OM. (Adapted from Casselbrant ML, Mandel EM. Acute otitis media and otitis media with effusion. In: Flint W, et al, eds. *Cummings otolaryngology—head and neck surgery*, 5th ed. Philadelphia, PA: Mosby Elsevier, 2010.)

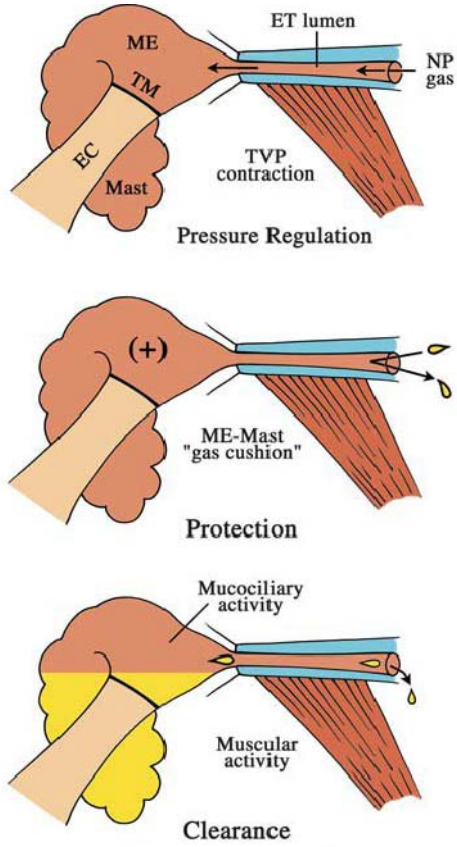

Figure 99.4 Functions of the eustachian tube (ET)–middle ear (ME)–mastoid (mast) gas cell system. Pressure regulation function is related to active dilation of the tube by contraction of the tensor veli palatini muscle (TVP) (*upper figure*). Protective function is dependent, in part, on an intact middle ear and mastoid gas cells to maintain a gas cushion (*middle figure*). Clearance function is enhanced by mucociliary activity and muscular activity during tubal closing (*lower figure*). EC, external canal; NP, nasopharynx; TM, tympanic membrane. In: Bluestone CD. *Eustachian tube: structure, function, role in otitis media.* Hamilton, ON: BC Decker, 2005:51.

could not equilibrate negative pressure. Children ages 3 to 6 years performed worse than children ages 7 to 12 years. These studies indicate that in even apparently otologically normal children, eustachian tube function is worse than in adults, but it does improve with age. The improvement in the eustachian tube function parallels the decrease in the incidence of OM. Stenström et al. (79) tested eustachian tube function in 50 otitis-prone children and 49 children with no history of AOM (controls) using a pressure chamber. The otitis-prone children had significantly poorer active tubal function than the normal controls, suggesting that recurrent AOM is the result of functional obstruction of the eustachian tube.

The forced response test (FRT) is designed to measure the passive and active function of the eustachian tube. In a recent pilot study, the FRT was used to test 3-year-old children 3 months after tympanostomy tube insertion with chronic OME (17 children, 24 ears) or recurrent AOM (15 children, 22 ears). The passive resistance and one measure of active function were significantly higher in the recurrent AOM group. The frequency of tubal dilation was not significantly different between the groups (80). However, based on the high variability in all the test parameters, the authors dismiss the possibility that an individual can be assigned to a particular disease expression based on the FRT test.

Infection

Bacteriology

Prior to the year 2000, studies in the United States reported that *S. pneumoniae* was the single most common bacterial pathogen in AOM, followed by *Haemophilus influenzae* and *Moraxella catarrhalis, Streptococcus pyogenes,* and other miscellaneous bacteria accounted for just a few cases. From ears with chronic OME, *H. influenzae* was the single most common pathogen, followed by *S. pneumoniae, M. catarrhalis,* and other bacteria accounting for a small percentage of cases each. Prevnar, a heptavalent conjugated pneumococcal vaccine (PCV7) for infants and young children, was licensed in the United States in 2000. Casey and Pichichero (81) examined the experience of children in a suburban Rochester, NY, practice in the years 2001 to 2003 (after the introduction of PCV7) compared to the years 1995 to 2000 and reported a 24% decrease in persistent AOM and AOM treatment failures. They also reported a decrease in recovery of *S. pneumoniae* from the ears of such children and an increase in *H. influenzae*. McEllistrem et al. (82) looked at middle-ear cultures obtained between 1999 and 2002 at five institutions. They reported that the percentage of AOM episodes due to non-PCV7 serogroups increased after 2000 from 12% in 1999 to 32% in 2002, and the nonvaccine serotypes were more frequent in those who received more than one dose of vaccine.

Nasopharyngeal carriage was also examined. Pelton et al. (83) enrolled 275 infants and children 2 to 24 months of age in a surveillance study in which nasopharyngeal swabs or nasal washes were obtained at all well-child visits and at visits for AOM. From 2000 to 2003, they noted a decrease in vaccine serotypes with an increase in nonvaccine serotypes. Tracking antimicrobial susceptibility, they found that the MIC50 and MIC90 for amoxicillin were stable until the last 6-month period when they both increased significantly. Jacobs et al. (84) examined the nasopharyngeal flora in children undergoing tympanostomy tube placement in March 2004 to March 2005 and also found a decrease in vaccine serotypes with a concomitant increase in nonvaccine serotypes, many of which were antibiotic-resistant strains.

Casey et al. (85) looked at the bacteriology of the nasopharynx and middle-ear fluid from children with no or infrequent episodes of AOM and from children with recurrent AOM during the years 2007 to 2009. Compared to their findings in 2001 to 2003, they found that, unlike shortly after the introduction of the conjugate pneumococcal vaccine, the frequency of non-PCV7 strains was nearly equal that of *H. influenzae*, with the nonvaccine serotypes, particularly 19A, replacing the vaccine serotypes. The frequencies of *S. pneumoniae* and *H. influenzae* were nearly equal, and the bacteria recovered from otitis-prone children were not different from that recovered from children with their first or second AOM episode.

Recently, a new vaccine with 13 serotypes of *S. pneumoniae* (PCV13) has replaced the 7-valent vaccine. In addition to the PCV7 strains, it includes serotypes 1, 3, 5, 6A, 7F, and 19A, which should add significant protection. As previously, there is a need for continued surveillance of the bacteriology of AOM with the use of this new vaccine.

Biofilms

Bacterial biofilms are sessile communities of interacting bacteria attached to a surface and encased in a protective matrix of exopolysaccharides rather than living in a motile "planktonic" or free-floating state. The matrix allows for protection from phagocytosis and other host defense mechanisms due to lack of accessibility by Igs and complement. The reduced metabolic rate of bacteria in the biofilm renders them resistant to antimicrobial treatment. The bacterial community relies on a complex intracellular communication system that provides for organized growth characteristics known as "quorum sensing." Biofilms have been known for a long time to exist on hard surfaces such as metal pipes, or teeth. Post et al. (86), using polymerase chain reaction methodology (PCR), found evidence of bacteria in 48% of culture-negative MEEs from children undergoing tympanostomy tube insertion for chronic OME. Hall-Stoodley et al. (87) obtained confocal laser scanning microscopy images from the middle-ear mucosa of 26 children scheduled for tympanostomy

tube insertion for recurrent/persistent OM and 8 controls (3 children and 5 adults) who underwent cochlear implants. Generic stains and species-specific probes for *H. influenzae*, *S. pneumoniae*, and *M. catarrhalis* were used to evaluate biofilm morphology. Mucosal biofilms were visualized in 92% of the mucosa from children with chronic and recurrent OM, but were not observed in any of the eight controls. The authors suggested that the findings supported the hypothesis that chronic middle-ear disease is biofilm-related. Biofilms have also been identified in the nasopharynx of children with OM, and it was suggested that the biofilm may act as a reservoir for bacterial pathogens resistant to antibiotics. The mechanical debridement of the nasopharyngeal biofilms may explain the observed clinical benefit associated with adenoidectomy in subsets of pediatric patients (88).

Nistico et al. (89), using a culture-independent molecular diagnostic methodology and confocal scanning, demonstrated that *H. influenzae*, *S. pneumoniae*, *M. catarrhalis*, and *S. aureus* were present in adenoids from children with "chronic otitis media" (rAOM and/or cOME) as well as in children with obstructive sleep apnea (OSA) in biofilm clusters on the mucosal surface and within adenoid crypts as well as intracellularly. The distribution of pathogens in the two groups was similar except that *H. influenzae* was significantly more common in children with chronic OM than in OSA (66.7% vs. 10%, $P = 0.005$).

Viruses

Until the introduction of PCR, viruses were not considered a major factor in the etiology of OM, probably due to technical difficulties in isolating the viruses. However, using the PCR technique, it has been possible to identify respiratory syncytial virus (RSV), influenza, adenovirus, parainfluenza, and rhinoviruses in MEE (65,90). There is strong evidence that viruses have a crucial role in the development of AOM (90). In the majority of children, viral infection of the upper respiratory tract mucosa initiates the whole cascade of events that finally leads to the development of AOM, and AOM may be regarded as a complication of a preceding or concomitant viral infection. In a study of 60 children (24 families) with at least 2 children between the ages of 1 and 5 years who were followed from October 2003 through April 2004 by daily parental recording of illness signs, weekly pneumatic otoscopy and viral PCR of nasal secretions collected during "colds" or when MEE was noted or from enrolled sibs without these conditions, one or more viruses were identified from 73% of secretions collected during a "cold" but from only 18% collected at a time without a "cold" (66). Of 93 episodes of OM (includes AOM and OME), 70% occurred during a "cold," and nasal secretions from 77% of children at the time of these episodes were positive for virus. For OM episodes, both with a "cold" and without, rhinovirus was the virus found most frequently; influenza and RSV were not found in episodes not associated with a "cold." When a virus was isolated from the nasopharynx with a cold or not, an associated episode of OM was classified as AOM in 8% of rhinovirus detections but in 33% and 38% of detections of RSV and influenza A virus, respectively (91). In a cohort of children 6 months to 3 years of age whose parents were instructed to present to the study when the child had a URI or AOM, Chonmaitree et al. (92) found AOM in 37% of URI episodes and OME in 24%. They found rhinovirus and adenovirus most commonly detected during URI, but the rate of OM associated with rhinovirus was lower than for other viruses.

Allergy and Immunology

Even though allergy is considered in the pathogenesis of OM, the causal mechanism is not understood, and well-controlled studies to prove the efficacy of antiallergic medication in the treatment of OM are lacking. Several mechanisms by which allergy may cause OM have been suggested: (a) the middle ear as a "shock organ" (target), (b) allergy-induced inflammatory swelling of the eustachian tube mucosa, (c) inflammatory obstruction of the nose, and (d) aspiration of bacteria-laden allergic nasopharyngeal secretions into the middle ear. The last three mechanisms involve an association between allergy and abnormal eustachian tube function. Prospective studies have reported a relationship between upper respiratory tract allergy and eustachian tube obstruction in a series of provocative, intranasal, allergen-inhalation challenge studies (93).

Recent studies focus on the analysis of the inflammatory markers in MEE to determine the role of allergy. Both Th (T-helper) 1 and Th2 inflammatory patterns have been found in OME. Th1 cytokines antagonize allergic inflammation and play a key part in the defense against viruses and intracellular pathogens, while Th2 cytokines promote IgE production, eosinophil growth, and mucus production (94). The chemoattractant cytokine RANTES (regulated upon activation, normal T cell expressed and secreted) and eosinophilic cationic protein (ECP), signs of a Th2 process, were assessed in MEE samples from 25 children with allergy and 20 nonallergic children, aged 5 to 11 years at the time of tympanostomy tube insertion (95). RANTES as well as ECP were significantly higher in the MEE samples from children with allergy than children without allergy ($P < 0.01$; $P < 0.05$, respectively). There was also a positive correlation between RANTES and ECP in MEE ($P < 0.01$) in children with allergy, which suggests that allergy is a contributing factor in the pathogenesis of OM.

Children with major immune deficiencies may have recurrent OM as part of their overall clinical picture, but most otitis-prone children may have only a subtle immunologic abnormality that predisposes them to recurrent infections (96). The three major OM pathogens—*S.*

pneumoniae, H. influenzae, and *M. catarrhalis*—frequently colonize the nasopharynx. There are many different strains of these organisms, and among the different strains, there are heterologous surface (strain-specific) antigens and conserved antigens. Conserved antigens induce broadly protective antibodies while strain-specific antigens induce limited protection. Otitis-prone children may display strain-specific immunity but fail to develop a broadly protective antibody response, which makes them susceptible to recurrent and persistent OM (97).

Recurrence of bilateral OME after tympanostomy tube insertion was more likely in children with poor eustachian tube function and low IgA or low IgG2 and decreased levels of mannose-binding lectin than in children with poor tubal function and high IgA and IgG2 measured at time of tube insertion (98). This suggests that an interaction between various immune factors may increase the risk for the development of OM.

Gastroesophageal Reflux

In 2002 Tasker et al. (99) reported finding pepsin/pepsinogen, using enzyme-linked immunosorbent assays, in 90.8% of 65 MEE samples obtained at the time of myringotomy in children. The pepsin/pepsinogen levels ranged from 0.8 to 213.9 μg/mL, which is 1,000 times higher than serum levels. He et al. (100), using a sensitive and specific pepsin assay, detected pepsin activity in 14.4% of 152 subjects undergoing tympanostomy tube insertion. The levels of pepsin ranged from 13 to 687 ng/mL. O'Reilly et al. (101) found pepsin in the middle-ear cleft of 20% of children (14% of ears) undergoing tympanostomy tube insertion for OM, compared to 1.4% of control children (1.5% of ears) undergoing cochlear implant who did not have a history of OM. Children with purulent effusions were more likely to have pepsin than those with mucoid or serous effusion (47% vs. 20% vs. 27%, respectively).

A prospective, uncontrolled before-and-after intervention study was performed in children with OM and GERD (102). Thirty-seven of the forty-seven entered children were evaluated 8 to 12 weeks following antireflux therapy (lansoprazole in the morning with ranitidine or nizatidine at bedtime) and were found to have improvement in hearing, quality of life scores, reflux questionnaires, fiberoptic laryngoscopy, otoscopy, and tympanometry.

PREVENTION OF DISEASE

Management of Environmental Factors

Promotion of breast-feeding in the first 6 months of life, avoidance of supine bottle feeding and pacifier use, and elimination of passive tobacco smoke may be helpful in reducing the risk of development of OM. Alteration of child care arrangements such that the child is exposed to fewer children may also be of benefit.

Vaccines

The three most common bacteria isolated from the middle ear are *S. pneumoniae, H. influenzae,* and *M. catarrhalis*. Presently, the *S. pneumoniae* vaccines (Pneumovax, Prevnar, and Prevnar 13) are the only bacterial vaccines available in the United States for OM. Although respiratory viruses, such as RSV, influenza, adenovirus, parainfluenza, and rhinovirus, have been isolated in MEE using PCR, influenza vaccine is the only available recommended viral vaccine today that may impact OM.

Bacterial Vaccines

Streptococcus pneumoniae

Pneumovax is a 23-valent polysaccharide vaccine [PPSV23], which is not efficacious in children 2 years or younger due to poor antibody production. *Prevnar is a* conjugated vaccine in which pneumococcal polysaccharides are conjugated to a nontoxic mutant of diphtheria toxin. The 7-valent vaccine (PCV7, serotypes 4, 6B, 9V, 14, 18C, 19F, 23F) was licensed for use in the United States in 2000 and recommended for use in children less than 6 years of age by the American Academy of Pediatrics (103). Prevnar 13 (PCV13) replaces PCV7. It was licensed for use in 2010 and includes six additional serotypes (1, 3, 5, 6A, 7F, and 19A) that can cause invasive pneumococcal disease, including the increasingly drug-resistant serotype 19A. The PCV 13 vaccine is recommended for all children 2 to 59 months of age and for children 60 to 71 months of age with an underlying condition that makes them more susceptible to pneumococcal disease. Children up to age 59 months who are fully (four doses) vaccinated with PCV7 should receive one dose of PCV13. (For further guidance by the American Academy of Pediatrics on use of PCV13 and PPSV23, see the Policy Statement, www.pediatrics.org/cgi/doi/10.1542/peds.2010-1280.)

There was great hope that the introduction and subsequent use of PCV7 for infants and young children would lead to a substantial decrease in AOM. Data from vaccine trials conducted in California (104) and Finland (105) revealed only a 7% and a 6% relative reduction, respectively, in AOM episodes. However, in the California study, children with recurrent OM benefited from the vaccine with a reduction of OM episodes varying from 9.3% to 22.8%, increasing as the frequency of episodes of AOM increased. In addition, immunized children were 20.1% less likely to require tube placement than controls. The PCV7 vaccine demonstrated a much higher efficacy (greater than 80%) in reducing invasive pneumococcal disease than reducing the burden of OM. Additional follow-up of the study subjects continued to demonstrate a modest amount of protection against episodes of AOM and tympanostomy tube insertion (106). Reduction in need for tympanostomy tubes after introduction of PCV7 was also shown in Tennessee and New York (107) and in Finland (108).

With use of the vaccine, pneumococcal colonization in the nasopharynx has changed as the vaccine has caused a reduction in the carriage rate of vaccine serotypes and replacement with nonvaccine serotypes (84,109). It should be noted that a reduction in nasopharyngeal carriage of vaccine serotypes and an increase in nonvaccine serotypes have also been seen in children younger than 7 months of age (83).

In the United States and Finland, the initial immunization with PCV7 is at age 2 months based on the results from the clinical trials. However, the question of whether or not the results obtained in the Finnish and US trials could be extrapolated to older children who already had a history of recurrent episodes of AOM was addressed by Dutch and Belgian trials (110,111). Seventy-eight and three hundred and eighty-three children with documented histories of recurrent AOM were enrolled in the Belgian and Dutch studies, respectively. In both trials, children between 1 and 7 years were immunized at entry with PCV7 followed by a booster immunization with a 23-valent pneumococcal polysaccharide vaccine 7 months later and followed up for a total of 18 months in the Dutch and 26 months in the Belgian trial. The results from these two studies did not lend any support to the use of pneumococcal conjugate vaccine to prevent AOM in previously unvaccinated toddlers and children with a history of recurrent AOM. In the infant studies, the PCV7 immunization may prevent or delay nasopharyngeal colonization of the most frequent pneumococcal serotypes and consequently delay pneumococcal episodes of AOM until a later age. In older children, who already are carriers of pneumococci, there is rapid replacement of pneumococcal vaccine serotypes with nonvaccine serotypes.

An 11-valent polysaccharide pneumococcal serotype vaccine conjugated to *H. influenzae*–derived protein D was evaluated in a clinical trial conducted in the Czech Republic enrolling a total of 4,968 children who were followed to the end of the second year of life with middle-ear cultures when episodes of AOM were diagnosed (112). The vaccine reduced the overall incidence of AOM episodes by 33.6%. Vaccine efficacy was 57.6% for episodes of AOM caused by pneumococcal serotypes included in the vaccine and 66% for vaccine-related cross-reactive pneumococcal serotypes. There was no significant change in number of AOM episodes due to nonvaccine serotypes. Of great interest is that there was 35.3% efficacy against AOM episodes caused by nontypeable *H. influenzae*. These results indicate that using the *H. influenzae*–derived protein D as a protein for conjugation of pneumococcal polysaccharides not only allowed for protection against pneumococcal otitis but also against OM due to nontypeable *H. influenzae*. The use of the *H. influenzae*–derived protein D and the two additional pneumococcal serotypes probably explains the 33.6% reduction in all types of AOM episodes by the vaccine, which is significantly higher than in the previously mentioned trials of PCV7 (104,105).

Haemophilus influenzae

As nontypeable *H. influenzae* is the second most common bacteria isolated from middle-ear fluid in AOM, much effort has been channeled into developing an effective vaccine. Many different approaches using animal models have been used to develop vaccine antigens for nontypeable *H. influenzae*–induced OM, including the following proteins: outer membrane protein (OMP) P5, 26, P2, P6, Htr protein, protein D, phosphorylcholine (ChoP), detoxified lipooligosaccharides (dLOS), and type IV pili. However, for the first time, it was possible to demonstrate an effective *H. influenzae* antigen for OM in a clinical trial using an 11-valent vaccine with the pneumococcal capsular polysaccharides conjugated to protein D, an outer membrane protein of *H. influenzae,* as previously mentioned (112). Although the efficacy for episodes of AOM caused by *H. influenzae* was only 35.3%, the results indicate that it would be feasible to develop an effective vaccine for this pathogen.

Moraxella catarrhalis

Moraxella catarrhalis is the third most common bacteria isolated from the middle ear. While the frequency of *M. catarrhalis* infections has previously been rather modest, recent studies have indicated that the frequency of nasopharyngeal colonization with *M. catarrhalis* in children with OM increased with the widespread use of the pneumococcal conjugate vaccine (113). Therefore, in order to have the greatest impact on reducing OM episodes, the development of a vaccine that contains *M. catarrhalis*, as well as *S. pneumoniae* and *H. influenzae* antigens, is necessary. Very little progress has been made in defining the protective immune response in *M. catarrhalis*. However, protective immune responses to *M. catarrhalis* in adults with chronic obstructive pulmonary disease have been identified (114). Candidate *M. catarrhalis* vaccine antigens that have been shown to induce potentially protective responses include outer membrane protein OlpA, CopB, filamentous hemagglutinin (FHA-like protein), and lipooligosaccharides (LOS).

Viral Vaccines

Based on evidence regarding the role of viruses in the pathogenesis in AOM, the development of viral vaccines should be strongly promoted (90). It should be recognized that bacterial vaccines only prevent the bacterial complications of a viral infection, while viral vaccines act at an earlier stage in the pathogenesis of AOM. Thus, viral vaccines have the potential to prevent viral URIs, thereby potentially preventing the development of AOM as a complication of bacteria in the nasopharynx.

Influenza Vaccine

The only commercially available viral vaccine today used for prevention of OM is the influenza vaccine, which is recommended for all children 6 months of age and older by the American Academy of Pediatrics Committee on

Infectious Diseases (115). Currently, there are two types of influenza vaccine available for children. Trivalent inactivated influenza vaccine (TIV) contains killed viruses and is given intramuscularly to children 6 months and older and adults. Live attenuated influenza vaccine (LAIV) is given intranasally and is currently licensed by the Food and Drug Administration for healthy individuals 2 through 49 years of age. A multicenter study enrolled and randomly assigned 8,475 children 6 to 59 months of age in a double-blind fashion to intranasal LAIV or TIV intramuscularly to assess the efficacy and safety of the vaccines (116). The LAIV was overall superior to the inactivated vaccine in preventing influenza episodes. There were 54.9% fewer cases of culture-confirmed influenza episodes in the group that received the LAIV ($P < 0.001$). The superior efficacy of LAIV was observed for both antigenically well-matched and drifted viruses. Rates of wheezing and hospitalization were higher in the youngest children who received the live attenuated vaccine compared to the inactivated vaccine.

For children younger than 6 months who are too young to receive any of the approved vaccines, it is recommended that close contacts be immunized to help protect those young children (115). The efficacy of maternal vaccination during pregnancy for preventing influenza in their young infants has been studied but findings are inconsistent. Although the U.S. Advisory Committee on Immunization Practices and the American College of Obstetricians and Gynecologists have recommended influenza immunization for all pregnant women in any trimester since 2004, only 10% to 40% of pregnant women are immunized. A study to look at the efficacy of maternal influenza vaccination is in progress (117).

A prospective study in children 13 years or younger was conducted during two respiratory seasons in Finland (118). The average annual rate of influenza was highest (179 cases/1,000 children) among children younger than 3 years of age. AOM developed as a complication of influenza in 39.7% of children younger than 3 years of age. For every 100 influenza-infected children less than 3 years of age, there were 195 days of parental loss of work (mean 3.2 days). The investigators concluded that vaccination of children less than 3 years of age might be beneficial to reduce the direct and indirect costs in children.

Two clinical trials have addressed the efficacy of inactivated influenza vaccine in preventing OM. Hoberman et al. (119) conducted a randomized double-blind, placebo-controlled 2-year clinical trial in 786 children ages 6 to 24 months in Pittsburgh, PA. The investigator did not identify any significant reduction in the burden of AOM from administration of inactivated trivalent influenza vaccine. However, in the first year of the study, the efficacy of the vaccine against culture-confirmed influenza was 66%, while in the second year of the study, the efficacy was −7%. The low efficacy rate in the second year may be explained by the attack rate of influenza virus in the second year not reaching epidemic proportions compared to the first year (3.3% vs. 15.9%, respectively) in the placebo group. The second study was single-blinded and evaluated the efficacy of inactivated influenza vaccine in preventing OM. The study was carried out in 119 children ages 6 to 60 months in day care in Turkey. The efficacy of the vaccine against AOM, OME, and OM was 51%, 18%, and 18%, respectively (120).

Block et al. (121) identified eight randomized trials of efficacy of LAIV for AOM in children 6 to 83 months of age. In six studies, they found that LAIV reduced influenza-associated AOM by 85% compared to placebo. In two studies comparing TIV to LAIV, the reduction was 54%. The reductions trended higher in children 24 months and older compared to the younger children. In children who developed influenza despite vaccination, LAIV recipients also had less AOM, with a reduction of 38.2% compare to those who received placebo.

Respiratory Syncytial Virus Vaccine

The seriousness of RSV in infants and children and the need for an RSV vaccine are widely recognized. In addition to lower airway infections, the RSV virus is one of the major viruses contributing to the development of AOM (64). A clinical trial in the 1960s of a formalin-inactivated RSV vaccine led to exacerbated disease upon natural infection with virus and two deaths. Thereafter, live attenuated vaccines were investigated, but a vaccine that produces safe, long-lasting immunity to RSV is still not a reality (122). At present, costly antibody prophylaxis with RespiGam and Synagis is used to prevent severe lung disease in high-risk infants.

An alternative approach to preventing RSV infection is maternal immunization. Munoz et al. (123) conducted a study to assess safety and immunogenicity of an RSV purified fusion protein 2 (PFP-2) subunit vaccine in 35 pregnant women in their third trimester. The transplacental transfer of vaccine-induced maternal antibodies was efficient, and there was no increase in frequency or severity of respiratory tract infections in the immunized infants. The infants were born healthy, and no adverse events related to maternal immunization were documented. In an unrelated study, Stensballe et al. (124) found that infants less than 6 months of age with high levels of RSV neutralizing antibody from their mothers had fewer hospitalizations for RSV. At present, maternal immunization is not universally recommended.

TREATMENT

The treatment of OM involves medical and surgical therapies.

Acute Otitis Media

Observation

In an effort to reduce antibiotic use and stem increasing bacterial resistance, observation without use of antibiotics is listed as an option for selected children with AOM in the guidelines document published by the American Academy

of Pediatrics and American Academy of Family Physicians in 2004 (125). Children for whom this is an option are to be selected based on diagnostic certainty, age of the child, illness severity, and access to medical care. Severe disease is defined as moderate to severe otalgia, fever greater than 39°C (102°F) orally or 39.5°C rectally, or a toxic appearing child. Children less than 6 months of age should be treated with antibiotics regardless; healthy children 6 to 23 months with nonsevere disease *and* an uncertain diagnosis could be observed, but if AOM is certain or severe, the child should be treated with antibiotics; and children 24 months or older could be watched if disease is nonsevere *or* the diagnosis is uncertain but treated if AOM is severe.

Already a popular method of management in several countries outside the United States, observation or "watchful waiting" is predicated on the results of several earlier studies showing the high spontaneous cure rate of AOM (126–131). Wald (132), however, cited problems with the earlier studies: The definition of AOM used in the various studies may have allowed for the inclusion of subjects with asymptomatic OME; children less than 2 years of age were not included in some studies and were underrepresented in others; the sickest children were often not selected for these studies; and the antibiotic selected may have been inappropriate and the doses used were often insufficient, all of which would make the efficacy of antimicrobial treatment appear lower. A metaanalysis of studies of AOM with an observation group found that children with bilateral AOM, especially those less than 2 years of age, were more likely to have prolonged symptoms when not given antimicrobial treatment (133). Recommendations for absolute and relative contraindications for observation without antimicrobial therapy are seen in Table 99.1.

Nonetheless, the practice of not treating AOM immediately with antibiotics, often giving a "backup" prescription in case of persistence of symptoms, is undergoing further scrutiny in this country and elsewhere. McCormick et al. (134) reported their randomized trial of immediate antibiotics plus symptom medication versus symptom medication only in 223 subjects with "nonsevere" AOM, of whom 57% were less than 2 years old. At day 12, 69% of TMs and 25% of tympanograms were considered to be normal in the antibiotic group, compared to 51% of TMs and 10% of the tympanograms in the nontreated group; 66% of the watchful-waiting group completed the study without antibiotics. Nasopharyngeal cultures at day 12 of the study revealed that *S. pneumoniae* was eradicated in most of the antibiotic-treated subjects, but the strains that were cultured were more likely to be antibiotic-resistant. Parental satisfaction with the assigned "treatment" was the same in both groups. Spiro et al. (135) randomly assigned children 6 months to 12 years of age diagnosed with AOM (definition left to discretion of physician) to either immediate antibiotic treatment or a "wait-and-see" prescription, to be filled if the child was not improving or was worse at 48 hours. Performed in an emergency room population, the mean age of subjects was 3.2 years; approximately 84% had unilateral AOM. The investigators found that 62% of the group given instructions to delay filling the prescription did not fill the prescription compared to 13% given the instructions to start the medication immediately ($P < 0.001$). The presence of fever and/or otalgia was associated with filling the prescription.

Vernacchio et al. (136) surveyed physicians in a national practice–based pediatric research network regarding their preferred management of AOM. In spite of the studies showing that the use of observation or delayed prescribing may allow for spontaneous recovery in many children and the option of observation was offered in the AOM guidelines, they found that while 83% considered observation a "reasonable option," it was used only in a median of 15% of cases.

The option of observation/no antibiotic treatment in young children was recently challenged by two clinical trials of antibiotic versus placebo. Hoberman et al. (137) undertook a randomized placebo-controlled trial to assess the extent to which antimicrobial treatment affects the course of symptoms and signs in children age 6 to 23 months of age with a certain diagnosis of AOM. Children were randomly assigned to amoxicillin–clavulanate (90 mg/kg/day of the amoxicillin component in two divided doses for 10 days) or placebo. There was no significant dif ference between the amoxicillin–clavulanate and placebo groups in regard to initial resolution of symptoms but sustained resolution (two successive days of recording a low symptom score) at days 2, 4, and 7 occurred earlier in the amoxicillin–clavulanate group than the placebo group (20, 41, 67% vs. 14, 36, 53%, respectively, $P = 0.04$). The rate of clinical failure (persistence of symptoms and/or signs) was lower among children treated with amoxicillin–clavulanate than placebo before the visit on day 4 or 5 (4% vs. 23% respectively, $P < 0.001$) and before visit day 10 to 12 (16% vs. 51%, respectively, $P < 0.001$). Tähtinen et al. (138) from Finland published a similar randomized placebo-controlled clinical trial also using amoxicillin–clavulanate (but at 40 mg/kg/day for the amoxicillin component for 7 days) in children ages 6 to 35 months to assess the efficacy of antimicrobial treatment of AOM when strict diagnostic

TABLE 99.1 CONTRAINDICATIONS FOR AOM OBSERVATION

Absolute contraindications

- Age <6 mo
- Immune deficiency or disorder
- Severe illness or treatment failure
- Inability to ensure follow-up and rescue antibiotic

Relative contraindications

- Relapse within 30 d
- Otorrhea
- Bilateral AOM if age <2 y
- Syndrome, craniofacial malformation

criteria are used as well as adequate active treatment. There were fewer treatment failures (a composite outcome of six components) in children receiving amoxicillin–clavulanate compared to placebo (18.6% vs. 44.9%, respectively, $P < 0.001$), and this was apparent already at day 3 (13.7% vs. 25.3%, $P < 0.001$). Overall, amoxicillin–clavulanate reduced the need for rescue medication by 81%. Diarrhea was significantly more common in the amoxicillin–clavulanate children than those treated with placebo (47.8% vs. 26.6%, $P < 0.001$). While these studies show an advantage of antimicrobial treatment in these young children, not all subjects given only placebo did poorly. Further studies will be needed to define the group requiring antibiotic treatment and the group that may do well without antibiotic; presently, these groups cannot be distinguished.

Pain Medication

The guidelines (125) strongly recommended treatment to reduce pain in children with episodes of AOM, which was based on randomized clinical trials with limitations and a relative balance of benefits and risk.

Antibiotics

While antibiotics remain the mainstay of treatment of AOM, there are considerable efforts to reduce the inappropriate use of antibiotic through better diagnostic skills in distinguishing AOM from OME, for which antimicrobial treatment is not now indicated, and in being able to identify the subgroup of children with AOM who will do well without antibiotic treatment. Many antibiotics are available, but according to the AAP-AFP guidelines (125), amoxicillin is still the first-line antibiotic for nonsevere episodes of AOM and, recommended at 90 mg/kg/day in two divided doses, is aimed at covering for *S. pneumoniae*, including resistant strains. For severe episodes of AOM, amoxicillin–clavulanate (amoxicillin 90 mg/kg/day and clavulanic acid 6.4 mg/kg/day in two divided doses) is recommended and will provide coverage for beta-lactam–producing *H. influenzae* and *M. catarrhalis*. According to these guidelines, cephalosporins should only be considered as accepted first-line treatment for patients with penicillin allergy. Macrolides should be prescribed for patients with penicillin and cephalosporin allergies. The child is considered a treatment failure if symptoms and signs persist/recur 48 to 72 hours after initial treatment assignment. The diagnosis should then be reassessed to confirm the diagnosis of AOM and antibiotics started if not given previously or changed to a more broad-spectrum agent if antibiotics were previously prescribed (amoxicillin–clavulanate if amoxicillin failed and ceftriaxone for 3 days if amoxicillin–clavulanate failed). Pichichero and Reed (139) reviewed the literature on amoxicillin absorption and found high variability in children, such that poor intestinal absorption may be responsible for some of the treatment failures with this drug. Tympanocentesis should always be considered if the child does not respond to the antibiotic treatment in order to identify the bacteria in the middle-ear effusion and select an appropriate antibiotic.

Duration of Treatment

Ten days of antibiotic treatment has been the standard, but in an effort to reduce cost and the incidence of antibiotic resistance, the efficacy of shorter courses has been investigated. Studies have found the 10-day course has resulted in fewer early treatment failures in younger children (36), in children recently treated for AOM (140), and in those presenting with spontaneous perforation of the tympanic membrane (141) compared to a 5-day course. The recent US guidelines (125) recommend the standard 10-day course of therapy for younger children and for children with severe disease, while for those 6 years of age and older with mild to moderate disease, a 5- to 7-day course may be used. Several short courses of antibiotics have been approved by the FDA for use in AOM. Cefpodoxime proxetil and cefdinir have been approved for a 5-day course; azithromycin may be given for 1-, 3-, and 5-day courses; and one dose of IM ceftriaxone may be given, although results for penicillin-resistant *S. pneumoniae* are better with a 3-day course (142).

Longer courses of antibiotics have also been proposed. In a randomized, double-blind trial of 10 days of amoxicillin versus 20 days of amoxicillin or 10 days of amoxicillin with an additional 10 days of amoxicillin–clavulanate, no advantage in treatment failure or duration of MEE was found with the longer courses (143).

Decongestants/Antihistamines

A metaanalysis of studies of decongestants and/or antihistamine for AOM found little clinical benefit of these medications for AOM persistence, symptoms, or longer-term sequelae. Although some benefit of the combination was found in the number of subjects with persistent AOM at the 2-week end point, the five- to eightfold risk of side effects and the fact that finding benefit was inversely correlated with study quality led the authors to not recommend the routine use of decongestant/antihistamine for AOM (144). In 1994, Chonmaitree et al. (145) reported increased levels of histamine in middle-ear fluid from children with AOM and speculated that antihistamine may be clinically beneficial in reducing inflammation. However, antihistamine administered with an antibiotic for AOM did not result in improved clinical outcome and prolonged the duration of effusion (146). At this point, neither decongestants or antihistamines, nor their combinations, are recommended for the treatment of AOM.

Steroids

Studies in rats suggested that steroid given with antibiotic reduced inflammatory changes in the middle-ear mucosa to a greater extent than treatment with antibiotic alone (147).

McCormick et al. (148) found no reduction in histamine or leukotriene B4 in children treated with oral antibiotic and steroid compared to children receiving antibiotic alone but did find a lower rate of treatment failure during the first 2 weeks and a shorter duration of MEE in those treated with steroid. However, when a larger sample of subjects was studied, the same group found that corticosteroid (2 mg/kg given for 5 days) administered with antibiotic did not provide any improvement in clinical outcome (146).

Recurrent Acute Otitis Media

Antibiotic Prophylaxis

There have been many studies of the efficacy of antibiotics to prevent AOM in children with frequently recurrent episodes. Many antibiotics have been studied, particularly amoxicillin and sulfisoxazole, used at half their recommended daily dose given once per day for months. Studies have generally concluded that antimicrobials are effective in preventing disease (149). However, this method of managing children with recurrent AOM is not recommended because of the potential for increasing resistant organisms. Rather than daily medicine given for months at a time, treating intermittently at the time of upper respiratory tract symptoms has been tried, but efficacy is less than with continuous medication (150).

Other Preventatives

Other medications/substances have been tried in an effort to prevent recurrent AOM, including xylitol (151,152), propolis and zinc (153), and osteopathic manipulation (154), but further studies are needed to define their role, if any, in the prevention of AOM.

Surgical Treatment

Myringotomy/Tympanocentesis

For episodes of AOM, a myringotomy/tympanocentesis is helpful for relief of pain and allows samples to be obtained for culture to identify the pathogen and to guide in the selection of antibiotics but provides no advantage in duration of effusion or recurrence of episodes of AOM (128).

Myringotomy with Tympanostomy Tube Insertion

Myringotomy and tympanostomy tube insertion (M&T) is currently the most common surgical procedure in children that requires general anesthesia. The rationale for tympanostomy tube insertion is promotion of ventilation of the middle ear and drainage through both the eustachian tube and the tympanostomy tube. Also, the aeration of the middle ear may promote normalization of the middle-ear mucosa. The removal of MEE restores conductive hearing. However, reflux of nasopharyngeal secretions may occur in an ear with a tympanostomy tube, causing otorrhea due to loss of the middle-ear air cushion effect.

When preventive and medical treatments for recurrent AOM (usually defined as three or more episodes in 6 months or four or more episodes in 12 months) have failed, tympanostomy tube insertion is recommended. A randomized clinical trial to evaluate the efficacy of M&T versus sulfisoxazole prophylaxis versus placebo enrolled 65 children 4 years or younger with recurrent AOM and followed them for 6 months or longer (155). Treatment failure was defined as two episodes of AOM or otorrhea in less than 3 months. In the M&T group, 5 of 22 children failed compared to 12 of 20 children in the placebo group ($P = 0.02$) and 8 of 21 children in the prophylaxis group. In a similar study to determine the efficacy of amoxicillin prophylaxis versus M&T versus placebo, 264 children ages 7 to 35 months with recurrent AOM were randomized to one of the three arms and followed for 2 years (156). The average proportion of time with OM (AOM and/or otorrhea) was 10% in the amoxicillin, 15% in the placebo, and 6.6% in the tube groups (placebo vs. tube; $P < 0.001$). Rates of new episodes of any type per child were 0.6 in the amoxicillin, 1.08 in the placebo, and 1.02 in the tube groups (amoxicillin vs. placebo; $P < 0.001$). The low rate of new episodes must be viewed in light of the fact that the study subjects proved not to be at as high risk of AOM as had been anticipated. However, compared to placebo, children with tympanostomy tubes spent less time with OM. It should be kept in mind that episodes of otorrhea with tympanostomy tubes are usually less severe, without fever and otalgia, and in most cases resolve with ototopical drops and do not require oral antibiotics.

Adenoidectomy with and without Tonsillectomy

The rationale for removal of the adenoids in children with OM is that the enlargement of the adenoids may cause obstruction of the nasopharynx and blockage of the eustachian tube, preventing ventilation of the middle ear/mastoid system (157). Also the adenoid tissue in children with OM has been found to have increased bacterial colonization, which may predispose to recurrent infections (158). Coticchia et al. (88) have demonstrated that the adenoids are covered with biofilm and may act as a reservoir for bacteria causing middle-ear disease. This may explain the improvement in the condition after mechanical debridement of the adenoids has been performed. The effect of adenoidectomy for OM is independent of the size of the adenoids (159,160).

Two parallel randomized clinical trials compared the efficacy of adenoidectomy (A) and adenotonsillectomy (AT) in 461 children ages 3 to 15 years with persistent and/or recurrent OM who had not previously undergone tympanostomy tube placement (161). Children without recurrent throat infections were randomized to A, AT, or no surgery (no A or AT) and children with recurrent throat

infections to AT or no surgery. The majority of children (91%) had a history of recurrent AOM. The efficacy of surgery in both trials was modest and limited mainly to the first follow-up year. The largest difference was in the three-way trial between AT and no surgery with a mean annual AOM rate of 1.4 versus 2.1 ($P < 0.001$) and mean estimated percentage of time with OM of 18.6% versus 29.9% ($P = 0.002$). Based on the short-term efficacy of A and AT as well as the morbidity and cost of these procedures, it was suggested that neither procedure should be considered as the initial surgical procedure.

In a randomized clinical trial assessing the efficacy of adenoidectomy versus placebo versus long-term antimicrobial prophylaxis in preventing episodes of recurrent AOM, 180 children ages 10 to 24 months were enrolled and followed for 24 months. No significant differences were observed between the groups in the number of episodes of AOM, visits to doctors, antibiotic prescriptions, and days with symptoms of respiratory infection. The authors concluded that adenoidectomy cannot be recommended as the primary treatment in this age group of children (162).

Hammaren-Malmi et al. (163) conducted a clinical trial in children 12 to 48 months of age with recurrent AOM (≥3 episodes in 6 months or ≥5 episodes in 12 months) to evaluate the efficacy of adenoidectomy in children receiving tympanostomy tubes. The children were randomized to tympanostomy tube insertion with (M&T-A) and without (M&T) adenoidectomy and followed for 12 months. During follow-up, the mean number of AOM episodes was 1.7 in the M&T-A children compared to 1.4 in the M&T children. The authors concluded that adenoidectomy at time of tympanostomy tube insertion does not significantly reduce the incidence of AOM in otitis-prone children younger than 4 years of age.

Adenoidectomy may provide modest improvement in children with recurrent AOM but is not recommended as a first-line procedure unless indicated for airway obstruction. Tonsillectomy, in conjunction with adenoidectomy, provides no significant advantage compared to adenoidectomy alone and the risks outweigh the benefits.

Otitis Media with Effusion

Observation

Because of the high spontaneous resolution rate of OME episodes (164), "watchful waiting" should be considered for children not at risk for speech and language or learning disabilities as recommended by the OME guidelines (Table 99.2) (165). Hearing testing should be done if MEE persists for 3 months or longer or at any time that language delay, learning difficulties, or significant hearing loss is suspected. If the average hearing level is less than 20 dB, watchful waiting is suggested, but if it is greater than 40 dB in the better ear, surgery is recommended. For children with hearing levels in the better ear between 21 and 39 dB, management is based on the duration of effusion and severity of symptoms. For children not at risk, examination at 3- to 6-month intervals until the fluid has resolved is recommended. If persistent hearing loss and language or learning delays are identified or there are suspected structural abnormalities of the ear drum, surgical treatment may be considered (166).

TABLE 99.2 RISK FACTORS FOR DEVELOPMENTAL DIFFICULTIES[a]

- Permanent hearing loss independent of OME
- Suspected or diagnosed speech and language delay or disorder
- Autism spectrum disorder and other pervasive developmental disorders
- Syndromes (e.g., Down) or craniofacial disorders that include cognitive and linguistic delays
- Blindness or uncorrectable visual impairment
- Cleft palate, with or without syndrome
- Developmental delay

Medical Treatment

Decongestant/Antihistamine

Decongestant, with or without antihistamine, was a popular treatment for OME, but clinical trials found no efficacy of these medications (167–170). In studies of OME at the Children's Hospital of Pittsburgh, no efficacy of an oral decongestant–antihistamine combination either alone (171) or when given with an antimicrobial agent (172) was found.

Antibiotics

Antibiotics came into prominence as treatment for OME toward the end of the 1970s/beginning of the 1980s when studies showed the ineffectiveness of decongestant/antihistamine combination. In addition, although thought to be sterile, studies showed that MEE from asymptomatic children contained bacteria (173,174). Mandel et al. (172) reported the results of their double-blind, randomized trial in which 518 children with OME of varying durations were divided into three treatment groups: (a) amoxicillin (40 mg/kg/day) for 14 days plus a decongestant/antihistamine combination for 28 days, (b) amoxicillin for 14 days (plus placebo for decongestant/antihistamine) for 28 days, or (c) placebo for both amoxicillin and decongestant/antihistamine. At 4 weeks, the rate of resolution of MEE was twice as high in those treated with amoxicillin, with or without decongestant/antihistamine, as those who received placebo (percentages effusion-free: 31.6, 28.8, and

14.1 in the amoxicillin plus decongestant–antihistamine, amoxicillin alone, and placebo groups, respectively); the addition of the decongestant/antihistamine made no difference. Recurrence of effusion occurred in most subjects within 3 months after completing treatment. Other antibiotics, including amoxicillin–clavulanate, ceftibuten, and penicillin, have been tested in clinical trials to determine whether all antibiotics provided the same efficacy, but none has been clearly shown to have any long-term advantage over the others (175–177). Mandel et al. (178) compared the efficacies of cefaclor and erythromycin–sulfisoxazole to that of amoxicillin. Besides not being better than placebo, cefaclor and erythromycin–sulfisoxazole showed no increased efficacy at 2 and 4 weeks after starting treatment compared to amoxicillin. Antibiotic used in prophylactic doses (generally half the total daily dose used for AOM given once daily for months) has also been examined in the treatment of OME, but its efficacy is linked more to preventing AOM than treating OME (179). Despite short-term efficacy (149,180), antibiotics are not recommended for routine treatment of OME due to lack of long-term efficacy, the high spontaneous cure rate, and concern about overuse of antibiotics.

Steroids

Theoretically, glucocorticoids should be efficacious in the treatment of OME: the antiinflammatory properties due to inhibition of phospholipase A_2, which then inhibits formation of arachidonic acid and the subsequent synthesis of inflammatory mediators, upregulation of transepithelial sodium transport promoting fluid removal from the middle ear, and decreasing mucin production by suppressing MUC5AC (181). In clinical trials, systemic steroids have demonstrated an advantage in resolving MEE compared to placebo, but due to the high recurrence rate after treatment, steroids are not recommended for long-term management (182).

Because of the side effects with use of systemic steroids, especially for prolonged courses of treatment, other routes of administration have been investigated. Tracy et al. (183) used prophylactic antibiotics with and without (both an untreated group and a placebo group) intranasal beclomethasone to treat 59 children with chronic OME and recurrent AOM. While all groups improved initially, there was no difference among the groups as to OME resolution by the 12-week visit. Cengel and Akyol (184) found, in a nonblinded, randomized (every other subject assigned to active treatment with nasal mometasone spray for 6 weeks, others assigned to no treatment) study of patients with documented MEE of at least 3 months' duration, 42.2% of treated subjects resolved at 6 weeks compared to 14.5% of untreated subjects ($P < 0.001$); no long-term follow-up was reported. A more recent trial in 217 children found intranasal mometasone furoate ineffective for the treatment of OME (185).

Leukotriene Inhibitors

A small study of montelukast for OME was stopped early because of lack of efficacy (186).

Autoinflation

Popularized by Politzer over 100 years ago, devices to insufflate air through the eustachian tube have been tried for the treatment of OME. However, studies using a number of devices have failed to show consistent efficacy (187–190), and so autoinflation is not recommended for routine use at this time. In their metaanalysis, Perera et al. (188) concluded that because of its low cost and absence of adverse effects, autoinflation might be considered for use while awaiting spontaneous resolution of the effusion.

Surgical Treatment

Myringotomy

Myringotomy alone has been shown to be ineffective for long-term management and is not recommended for chronic OME (159,191). Laser-assisted myringotomy (OtoLAM) has been described as an alternative to the standard myringotomy in children with chronic OME, and the procedure can be done under local anesthesia and is considered safe. However, the mean time to closure of the perforation is only 2 to 3 weeks (192,193).

Myringotomy with Tympanostomy Tube Insertion

In children with persistent MEE, the decision of whether to insert tympanostomy tubes is based on the child's hearing status and risk for developmental problems. Several randomized clinical trials have demonstrated evidence-based indications for the use of tympanostomy tube insertion for chronic OME.

The efficacy of M&T for the management of OME has been the subject of many studies. Mandel et al. (194) reported the results of a 3-year clinical trial of 109 children, 7 months to 12 years of age, with OME of 2 months' duration or longer who were unresponsive to medical management and who were randomly assigned to receive myringotomy alone (M), M&T, or no surgery. During the first year, over 50% of subjects in the M and the no surgery groups met preset treatment failure criteria and underwent M&T. A second study (191) designed to correct some of the design flaws of the first study and to extend the time until treatment failure involved 111 children with OME for at least 2 months and whose pure-tone averages bilaterally were ≤35 dB. This study also found high rates of treatment failure in children in the M group (70%) and the no surgery group (56%). The percentages of time with MEE during the first year in the M, M&T, and no surgery groups were 61%, 17%, and 64%, respectively ($P < 0.001$). From these studies, it was concluded that M offered no advantage over no surgery in regard to percentage of time with effusion, number of AOM episodes, and number of repeat

surgical procedures and M&T provided more disease-free time and better hearing than M or no surgery.

Gates et al. (159) studied the effects of various surgical treatments in children 4 to 8 years of age with chronic OME; 127 children were randomly assigned to M and 150 were assigned to M&T. Compared to M only, M&T provided less time with effusion, more time with better hearing, and necessitated fewer surgical retreatments.

The previously mentioned studies (191,194) were performed at a time when it was considered "unethical" to allow a child to have MEE for more than 2 to 3 months because of the associated hearing loss and the possible detrimental effects on speech and language development. A more recent study by Paradise et al. (195) randomly assigned 429 children less than 3 years of age with persistent or recurrent OME to either prompt M&T or to M&T up to 9 months later. Eighty-five percent of children in the promptly treated group and forty-one percent of children in the late treatment group had undergone M&T by 6 years of age. On developmental testing at 6 years, there were no significant differences between the groups on 30 measures. Interestingly in both the randomized clinical trial and in children randomly selected from those followed in the study but did not meet criteria for randomization, sociodemographic variables seemed to be the most important factors influencing developmental outcomes.

Adenoidectomy

A study by Maw (196) enrolling children 2 to 11 years of age with chronic OME showed that adenoidectomy (A) alone and M&T alone provided better results than no surgery, but the combination of the two surgical procedures provided better results than either alone. The addition of tonsillectomy to adenoidectomy provided no additional benefit for middle-ear fluid resolution. In the previously discussed study by Gates et al. (159), the children randomly assigned to the M-A and the M&T-A groups both had a lower percentage of time with effusion than those who received M&T alone. Thus, based on these results, Gates et al. recommended M-A as the "first-line" procedure.

Paradise et al. (160) studied 213 children 1 to 15 years old with recurrent AOM or OME who had previously had M&T. Children were randomly assigned to adenoidectomy or no adenoidectomy; M&T was also performed at the same time for specific indications. Of the 99 subjects who were randomized, there was a significant reduction in time with OM during the first 2 years in the children who underwent adenoidectomy compared to those who did not. For the remaining children followed but whose parents chose not to allow random assignment, the results favored adenoidectomy compared to no adenoidectomy.

A clinical trial enrolling 98 children ages 24 to 47 months with bilateral OME for 3 months or longer, or unilateral for 6 months or longer, or after extrusion of prior tympanostomy tubes randomized the subjects to M&T versus M-A with and without insertion of tubes (197). In these young children, adenoidectomy with M&T provided no advantage over M&T alone in regard to mean percentage of time with MEE during the first 18 months (18.1% vs. 11.9%, respectively, $P = 0.21$) or the entire 36 months of follow-up (20.6% vs. 18.6%, respectively, $P = 0.87$). However, the mean percentage of time with MEE in the M-A group (35.7% by 18 months, 31.1% by 36 months) was significantly higher than in both the M&T and M&T-A groups ($P < 0.001$ and $P = 0.003$, respectively, at 18 months, $P < 0.001$ and $P = 0.02$ at 36 months). During the 36 month follow-up, M-A resulted in 24% of the children needing an additional procedure (M&T) compared to 29% in the two groups with initial M&T.

Several *retrospective* studies have looked at the efficacy of adenoidectomy in addition to M&T. Boston et al. (198) evaluated risk factors for additional tube insertion in 2,121 patients undergoing bilateral M&T. In 19.9% of the children, two or more tube insertions were performed. After the initial tube insertion, as many as 45.1% of the patients needed an additional surgical procedure (M&T, A, and/or tonsillectomy). Patients younger than 18 months at the initial procedure were significantly more likely to have a second procedure (26.3% vs. 15.9%, $P < 0.001$). Adenoidectomy was performed at the time of the initial M&T in 527 patients (24.5%). This reduced the probability of needing a second set of tubes (0.08 vs. 0.24, $P < 0.001$). Also the probability of needing a third set of tubes was reduced when adenoidectomy was performed at or before the second set of tubes (0.15 vs. 0.40, $P < 0.001$). The presence of craniofacial abnormalities and a family history of A, T, or M&T increased the risk of subsequent tube insertions ($P < 0.001$). Sex and race were not risk factors for subsequent tube insertion.

Another retrospective study evaluated the effect of adjuvant A or A-T at time of M&T on the rate of reinsertion of tubes and rehospitalization for OM-related conditions in 37,316 Canadian children (≥19 years) who received tubes as their first surgical procedure (199). As compared to tube insertion alone, A was associated with a reduction in the likelihood of reinsertion of tubes (RR 0.5, 95% CI: 0.5 to 0.6; $P < 0.001$) as was A-T (RR 0.5, 95% CI: 0.5 to 0.6; $P < -0.001$). Performing A or A-T at the time of the M&T substantially reduced the likelihood of additional hospitalization and operations related to OM among children 2 years or older.

A third large retrospective study assessing the benefits of adjuvant pharyngeal surgery (A, A-T, and T) at the time of M&T examined the records of 51,373 children less than 10 years of age (200). Twenty-nine percent of the children had pharyngeal surgery at the time of the first M&T. The

authors concluded that having A or A-T at the time of first or subsequent M&T was associated with reduced risk of further tube insertion.

Guidelines

In 2004 a revised Clinical Practical Guidelines for OME was published jointly by the American Academies of Family Physicians, Otolaryngology-Head and Neck Surgery, and Pediatrics (166). The guidelines were evidence-based and the quality of the evidence was assessed. The recommendations reflected the quality of the evidence and the balance between benefit and harm that is anticipated when recommendations are followed. The guidelines apply to children 2 months through 12 years with and without developmental disabilities or underlying conditions that predispose to OME and its sequelae. The decision regarding surgery for OME depends largely on hearing status, associated symptoms, the child's developmental risk (Table 99.2), and the anticipated chance of timely spontaneous resolution of the effusion. Surgical candidates are children with (a) OME lasting for 4 months or longer with persistent hearing loss or other signs or symptoms, (b) recurrent or persistent OME in at-risk children regardless of hearing status, and (c) OME and structural damage to the TM or middle ear.

Tympanostomy tube insertion is the initial preferred procedure. Adenoidectomy should not be performed unless a distinct indication exists (nasal obstruction, chronic adenoiditis). Repeat surgery consists of adenoidectomy plus myringotomy with and without tympanostomy tube insertion. Tonsillectomy alone or myringotomy alone should not be used to treat OME.

Quality of Life Assessment

The first validated quality of life (QOL) outcome study for OM was the OM-6 instrument developed by Rosenfeld et al. (201) representing six domains including physical stress, hearing loss, speech impairment, emotional distress, activity limitation, and caregivers' concerns. A large, moderate, or small improvement after M&T was documented in 56%, 15%, and 8% of children, respectively, using this instrument (202). Trivial changes were noticed in 17% of children, and 4% of children had a poor outcome after tube insertion. The results indicate that M&T produces large short-term improvement in QOL for most children.

A quality of life outcome study assessed the parents' appreciation of their child's general condition using the OM-6 scale before, after, and retrospectively before M&T in a group of Dutch children 12 to 36 months of age (203). The results from the retrospective assessment of the child's general condition prior to M&T indicated that the parents underestimated the effects of OM before surgery. In particular, following M&T, parents were able to appreciate the extent of presurgical hearing loss.

TYMPANOSTOMY TUBES

Selection of Tympanostomy Tubes and Indications

Many different tympanostomy tubes have been developed, but most tympanostomy tubes are variations of the grommet or the T-tube. The duration of time before extrusion is shorter for grommet tubes than for T-tubes. Weigel et al. (204) performed a randomized prospective trial of four different types of tympanostomy tubes in 75 children. During the first 2 years, 93% of Shepard tubes, 80% of Armstrong tubes, 66% of Reuter-Bobbin tubes, and 31% of Goode T-tubes had extruded. In studies from Pittsburgh, the tube life of the Armstrong-type tube was approximately 1 year; 50% had extruded by 12 months and 75% by 18 months (191). The time to extrusion is a function of the size, shape of the medial flange, absence of a lateral flange, and the material of the tube. Also the coating of the tube may affect the time to extrusion as it may prevent infections (205,206).

In a young child with a history of recurrent or persistent OM, a tympanostomy tube that remains in place for at least a year is preferable. If the child has recurrent OM after the tubes have become nonfunctional or extruded, a similar type of tube should be recommended. Grommets with shorter duration are recommended in older children who may not continue to have problems after the present season. T-tubes or long-term tubes are recommended for older children with persistent problems due to poor eustachian tube function. Also they are recommended for children who have an atrophic TM after multiple sets of tympanostomy tubes as a regular grommet tube may be very quickly extruded.

Peri- and Postoperative Ototopical Drops

In an effort to reduce early postoperative otorrhea and tube blockage, ototopical antimicrobial drops have been recommended to be placed at the time of surgery, especially if MEE was present (207,208). Only FDA-approved ototopical agents such as ofloxacin (Floxin) and ciprofloxacin with dexamethasone (Ciprodex) should be used.

Postsurgical Follow-Up

All patients should have a follow-up visit a few weeks after surgery for an otoscopic examination to assess the status of the tympanostomy tube. In addition, all patients should have an audiologic examination postoperatively to document that the hearing is normal. Patients are also usually evaluated 6 to 12 months after the insertion of the tubes

and every 6 months thereafter or when problems occur to assess the status of the tube and TM.

Complications and Sequelae of Tympanostomy Tubes

Otorrhea

Otorrhea through a tube or perforation is a common problem after M&T and has been recorded in as many as 50% of children with tympanostomy tubes (209). Transient otorrhea occurred in the postoperative period in 16% (range 8.8 to 42.0) and later in 26% (range 4.3 to 68.2) of patients; recurrent otorrhea occurred in 7.4% (range 0.7 to 19.6) and chronic otorrhea in 3.4% (range 1.4 to 9.9) of patients (210). If untreated, it can develop into chronic suppurative OM. Pathogens typical of AOM (*S. pneumoniae, H. influenzae, M. catarrhalis,* and *S. pyogenes*) were found in 42% and *P. aeruginosa* and *S. aureus* in 44% of all episodes of acute otorrhea in 246 children with tympanostomy tubes followed prospectively (208). The typical AOM pathogens were more common in children under 6 years of age than in older children (50% vs. 4.4%; $P < 0.001$). *P. aeruginosa* was more common in children 6 years or older than in the younger children (43.5% vs. 20.5%; $P = 0.052$). Roland et al. (211) recovered 1,309 isolates from 956 acutely draining ears and identified *S. pneumoniae* in 17%, *H. influenzae* in 18%, *S. aureus* in 13%, *P. aeruginosa* in 12%, and fungus in 5%. Several clinical trials have demonstrated that ototopical agents such as ofloxacin otic solution and ciprofloxacin–dexamethasone otic suspension are effective when acute otorrhea occurs through a tympanostomy tube or perforation, even when no systemic antibiotic is given (212). In a child who has severe systemic symptoms, a systemic antibiotic should be added. The ciprofloxacin–dexamethasone combination has been shown to be superior to ofloxacin in resolving granulation tissue (213). The use of other ototopical agents in a nonintact TM has not been approved by the U.S. Food and Drug Administration (FDA) as they can be ototoxic, especially those that contain aminoglycoside. If the drainage does not resolve in 7 to 10 days, suctioning of the ear canal should be performed, and a culture from the opening of the tube should be obtained to determine the causative pathogen. If yeast is the predominant organism, treatment with a topical antifungal drop such as clotrimazole should be initiated. Repeated aural toilet is a very important part of the treatment. However, it may be difficult for a child and the parent to comply with frequent suctioning. If aural toilet and topical treatment fail and the organisms are not sensitive to oral antibiotics, culture-directed intravenous antibiotics, removal of the tube(s), or rarely simple mastoidectomy should be considered. CT scan of the temporal bones should be obtained prior to possible mastoidectomy to look for complications such as coalescent mastoiditis. In older children with recurrent episodes of otorrhea, removal of the tubes is the treatment of choice, as in these children the eustachian tube may have matured and secretions from the nasopharynx may be refluxing into the middle ear. Also, the tube may occasionally act as a foreign body, causing a foreign body reaction with granulation tissue and infections. Recently, biofilms have been implicated (214).

Tympanosclerosis, Atrophy, and Retraction Pockets

A metaanalysis reviewing 134 articles estimated the incidence of TM sequelae after tube extrusion and reported that tympanosclerosis occurred in 32% (range 7.2 to 64.3), focal atrophy in 25% (range 1.6 to 75.0), and retraction pockets in 3.1% (range 0 to 22.7) of ears (210). The type of tube (short-term vs. long-term) had no significant impact on these rates.

The sequelae of M&T in children with chronic OME followed for 8 years was reported by Daly et al. (215). One hundred thirty-eight children (275 ears) followed for 3 years and eighty-four of these children (167 ears) followed for 8 years were evaluated in regard to TM myringosclerosis, atrophy, retraction pockets or perforations, hearing loss, and static admittance. In general, the annual incidence of sequelae was greater at the 4- to 5-year follow-up than at the 6- to 8-year follow-up. While atrophy developed in 67% of the ears, myringosclerosis in 40%, and perforation in 3% between the 3- and 8-year follow-up evaluations, the annual risk of new sequelae declined considerably throughout the 3- to 8-year follow-up for most sequelae studied. However, atrophy and pars tensa/flaccida retraction were present in 55% of ears at the 8-year follow-up, which may put children at risk for continuing middle-ear problems during adolescence and adulthood. These results support the need for long-term follow-up in selected patients.

Johnston et al. (216), reporting the incidence of TM abnormalities in children in the previously cited trial (195) of prompt versus delayed tube insertion, found that children who underwent intubation had more segmental atrophy and tympanosclerosis at age 5 years than children who did not receive tubes. There was no significant relationship between hearing levels at 6 years of age and the presence or type of TM abnormalities.

The overall prevalence of TM pathology was assessed in 168 subjects 25 years after M&T in the right ear and myringotomy (M) in the left ear for chronic OME (217). Myringosclerosis and late atrophy were more prevalent in M&T ears. Prevalence of TM retractions decreased over time, while myringosclerosis remained unchanged in M&T ears and increased in M ears. The extension of myringosclerosis increased in M&T ears, while atrophy and pars tensa retraction decreased over time regardless of treatment modality. Hearing, tympanometric pattern, and eustachian tube function were unrelated to prior treatment modality.

Persistent Perforation

The incidence of persistent perforation after extrusion of tympanostomy tubes has been estimated at 2.2% (range 0% to 12.3%) for short-term tubes and 16.6% (range 0% to 47.0%) for long-term tubes (210). The perforations caused by tympanostomy tubes are usually small and consequently hearing loss is very mild. The perforations are easily managed with a simple fat graft, gelfoam, or paper patch/Steri-strip myringoplasty. Sckolnick et al. (218) found that the success rate with gelfoam myringoplasty was higher than with fat graft or paper patch. Prior to closing the perforation, it is important to make sure that eustachian tube function is good; otherwise, there is a risk of nonclosure or reaccumulation of fluid in the middle ear. As a rule the TM in the opposite ear should be intact and free of infection for a year.

Cholesteatoma

For all types of tubes, the combined incidence of cholesteatoma is 0.7%, but for short-term tubes, the incidence is 0.8% (range 0% to 6.5%) and for long-term tubes 1.4% (range 0% to 3.0%) (210). There are several mechanisms responsible for the development of cholesteatomas. Tympanostomy tubes may be inserted to prevent the development of cholesteatoma in a retraction pocket. However, cholesteatoma may result from ingrowth or transplantation of keratinized epithelium into the middle-ear cleft around a tympanostomy tube. Also an intratympanic cholesteatoma may develop after surgical manipulation of the TM. Patients with tympanostomy tubes should be routinely followed during the time the tubes are in place and after extrusion to assess the TM and middle ear for cholesteatoma development.

Early Extrusion

Premature extrusion of tubes occurs in approximately 3.9% of ears (210). This is most likely due to infection in the middle ear that pushes the tube into the external ear canal. The tube may not have been properly inserted especially if the TM is thickened due to an infection at the time of tube insertion. An atrophic TM may also allow early tube extrusion.

Blockage of Tube

The lumen of the tympanostomy tube may become obstructed from dried blood or mucus, granulation tissue, or a polyp caused by infections in the middle ear. The incidence of plugging of the tube is 6.9% (range 0% to 37.3%) of ears (210). The tube can sometimes be unplugged using a pick, suction, or a Rosen needle or ototopical drops for 10 to 14 days. If the blockage cannot be resolved but the middle ear is effusion-free with normal middle-ear pressure, the tube can be left in place and watched until extrusion. On the other hand, if fluid has accumulated in the middle ear or recurrent infections continue, replacement of the tube should be considered.

Displacement of Tympanostomy Tube into the Middle Ear

The incidence of displacement of a tympanostomy tube into the middle ear is 0.5% (range 0% to 1.3%) (210). It occurs most commonly at the time of surgery, but it can also be seen later due to infection or trauma, which is very rare. If the tube is displaced into the middle ear during surgery, attempts should be made to retrieve the tube at the time of surgery. However, if a tube is visualized behind an intact TM, risks versus benefits have to be assessed as a child would require general anesthesia and an incision of the TM to retrieve the tube. A tympanostomy tube displaced behind an intact TM rarely causes problems.

Retained Tympanostomy Tubes

A tympanostomy tube is usually not removed surgically as most tubes extrude spontaneously. However, in some children, the tube remains in place in the TM and has to be removed surgically. Indications for removing a tympanostomy tube include:

- One tube is retained while the other tube has extruded and the middle ear has been free of disease for 1 year or longer in a child 5 to 6 years or older.
- Bilateral retained tubes in an older child with good eustachian tube function
- Chronic or recurrent episodes of otorrhea that are not able to be managed medically, especially in an older child who previously has not had recurrent episodes of otorrhea, as this could be a sign of reflux of secretions from the nasopharynx due to maturation of the eustachian tube
- The tympanostomy tube is imbedded in granulation tissue and the tube is blocked.

In children, most retained tubes are removed under general anesthesia. After the tube has been removed, a paper patch or gelfoam myringoplasty is performed. Soft long-term T-tubes may be removed in the office with older, cooperative children. These children must be followed to see if the perforation closes spontaneously or requires myringoplasty.

Water Precautions

Several studies have been published, including two meta-analyses (219,220) demonstrating no increase in episodes of otorrhea in patients with tympanostomy tubes not using water precautions compared to those using water precautions. In a clinical trial to assess the need for water precautions for children with tympanostomy tubes, 201 children, ages 6 months to 6 years, were randomized to swimming and bathing with and without ear plugs and followed monthly for 1 year and whenever an episode of otorrhea occurred (221). At least one episode of otorrhea was documented in 47% of children who used ear plugs

compared to 56% in children with no ear plugs ($P = 0.21$). The mean rate of otorrhea per month for children who used ear plugs compared to children not using ear plugs was 0.07 versus 0.10 ($P = 0.05$). Although children who do not use ear plugs have a higher incidence of episodes of otorrhea, the clinical impact of using ear plugs is small, and their use should be individualized rather than recommended on a routine basis.

A clinical survey was conducted in the Pacific Northwest to determine the recommendations given to parents/patients regarding water precautions for swimming with tympanostomy tubes (222). A total of 263 physicians returned the survey (23.5% response rate). Based on this study, most primary care physicians (83%) and approximately half of the otolaryngologists (47%) still recommend water precautions for swimming with tympanostomy tubes.

COMPLICATIONS OF OTITIS MEDIA

Judicious use of antimicrobial therapy, including observation without antimicrobials for AOM, has been promoted by guidelines in many different countries due to the development of increased bacterial resistance to the most common antibiotics. However, delaying antimicrobial therapy may increase the risk of development of complications. Schilder et al. (223) compared the national prescription rate of antibiotics for AOM and the national incidence rate of acute mastoiditis across countries. The study showed a slightly higher incidence rate of acute mastoiditis in children, that is, about 4 per 100,000 person years, in the Netherlands where only 31% of patients with AOM receive antibiotics as compared to 2 per 100,000 person years in the United States where almost all cases of AOM are treated with antibiotics. More recent studies have shown that use of antibiotics to treat AOM in children might not influence the subsequent development of acute mastoiditis (224). Also, there is no difference in the proportion of pediatric mastoiditis caused by *S. pneumoniae* in the preconjugated pneumococcal vaccine versus postvaccine eras (225).

Complications and sequelae of OM can be divided into intratemporal and intracranial (Table 99.3). The intratemporal and intracranial complications are rare in developed countries but are common in third-world countries. However, even though these may be rare in developed countries, they still remain a challenge when they arise and are associated with significant morbidity. Therefore, it is imperative that any physician or health care provider who cares for young children at risk for OM is vigilant with a high index of suspicion and has knowledge of the early signs and symptoms of potential complications, the diagnostic assessment including CT scan and MRI, and the indications for medical and surgical management (see Chapter 149).

Hearing Loss, Speech–Language, and Child Development

Most children with MEE have conductive hearing loss that can be fluctuating or persistent. It is usually a mild to moderate conductive loss averaging between 20 and 30 dB in the low to midfrequency range (226). Rarely, a permanent sensorineural hearing loss may result from AOM or OME, possibly due to spread of the infection through the round or oval windows, or a suppurative complication. However, behavioral hearing thresholds in the high frequencies (12 to 20 kHz) are significantly higher in children with histories of OM even when the middle ear is effusion-free (227–229). Many studies have investigated the association between OM and speech–language and child development. Some studies have found an association while others have failed to do so. Paradise et al. (230) reported that there was no difference between children with OM with early versus late tympanostomy tube insertion with regard to hearing, speech–language, and behavioral testing up to 9 to 11 years of age. Johnson et al. (231) also found no relation of MEE in the first 3 years of life to language outcomes at 7 years of age. However, as indicated in the OME Guidelines (166), it is recommended that each child with OME undergo hearing testing every 3 to 6 months and be assessed for tympanostomy tube placement if they are at risk for any developmental difficulties due to OM, such as significant speech delay.

A recent study assessing tympanostomy tube outcomes in children at risk and not at risk for developmental delays was performed using a Likert-type outcome questionnaire administered to the caregiver by telephone (86%) or mail (14%). Two hundred and twenty-nine children aged 0.5 to 13 years were eligible of whom 55% had at least one condition placing them at risk for developmental delays. The mean pure-tone average at baseline for the better-hearing ear was 32 dB HL. After tube insertion, 89% of caregivers stated that their child's life was "much better." Speech and language as well as learning and school performance was "much better" for 55% of the children, and this was more often in at-risk children. However, hearing improvement was reported by 84% with no relationship to at-risk status. Overall, caregivers reported favorable outcomes regardless of their child's at-risk status, but children at risk had better reported outcomes for speech, language, learning, and school performance (232).

Balance Problems

During an episode of MEE, balance and vestibular function seem to deteriorate, and when the effusion resolves or tympanostomy tubes are inserted, these functions improve (233). Also, children with OM may be more visually dependent as a result of the deterioration of vestibular function causing excessive reliance on other nonvestibular sensory cues to maintain balance (234).

Children may have delayed motor coordination skills such as walking or may be clumsy, which may make them more accident-prone. Stenström and Ingvarsson (235) reported that Swedish otitis-prone children were seen more often in the orthopedic and general surgery departments compared to children who were not otitis-prone.

HIGHLIGHTS

- The presence or absence of signs and symptoms and findings on the otoscopic examination provide the basis for diagnosis of the difference types of OM.
- Proper treatment depends on differentiation between AOM and OME.
- The highest incidence of OM occurs between the ages of 6 and 11 months and decreases with age.
- Risk factors include both host and environmental factors.
- Prevention of disease through use of vaccines and risk factor reduction is desirable.
- For children 2 years of age or older with nonsevere AOM, published guidelines have given the option of observing rather than treating with antibiotics immediately.
- Antihistamines and steroids are ineffective for the treatment of OM.
- Tympanostomy tube insertion is effective in reducing recurrent episodes of AOM and persistent middle-ear effusion.
- Adenoidectomy is not recommended for the initial surgical treatment of OM unless nasal obstruction is present but is recommended for children in whom a repeat surgical procedure is needed.
- Careful follow-up is needed to identify complications and sequelae of otitis media as well as of its treatment.

Pediatric Audiology and Implantable Hearing Devices

100

David H. Chi *Diane L. Sabo*

Universal newborn hearing screening (UNHS), the lower age of identification of hearing loss, and the need to move rapidly through the evaluation and management process have resulted in a change in pediatric audiology. The population of children who are referred for audiologic evaluations now has a higher percentage of young infants. This has resulted in a greater reliance on physiologic measures for hearing assessment and changed the counseling that needs to be done when hearing loss is identified. Prior to newborn hearing screening, most parents were referred or sought audiologic evaluations for their child who had delays in speech development. Now, with newborn hearing screening, the child presents soon after birth, and families have not had time to think about the possibility of hearing loss or the implications of their child having a hearing loss. The clinician has to consider the impact on the family that a child with a hearing loss can have. In addition, all members of the health care team need to work cohesively to unify terminology, results, and recommendations and to lessen any confusion the families may have when they hear differences. It is important, therefore, for the otolaryngologist and audiologist to have a close working relationship with respect to the diagnosis and ongoing treatment of children with hearing loss.

Congenital hearing loss occurs commonly and is more frequent than other conditions for which newborns are routinely screened (1). Data from newborn hearing screening programs show that the incidence of hearing loss is twice as high as all other diseases screened at birth, occurring in about 2 to 4 per 1,000 births compared to about 1.2 per 1,000 births for the combined totals for all other diseases (2–5). In the United States, about 8,000 to 12,000 babies are born each year with permanent hearing loss (compiled by the National Institute on Deafness and Other Communication Disorders [NIDCD]). When combined with progressive, unilateral, and conductive hearing loss, as many as 15 per 1,000 will have some degree of hearing dysfunction (6).

Hearing loss in infants, when left undetected, can affect speech and language acquisition leading to poor language and literacy skills. In addition, other areas can be impacted, including academic achievement and social and emotional development (7–11). If hearing loss is detected early, however, poor outcomes can be diminished, and even eliminated, through early intervention. Studies have shown that communication skills comparable to age-matched hearing peers can be achieved when hearing loss is identified early, and children receive early intervention services (12–15).

NEWBORN HEARING SCREENING

Identification of hearing loss in infants and children has gone through tremendous changes over the past 10 years. The single most influential reason for this change is UNHS. With implementation of UNHS, hearing loss is being identified at earlier ages compared to prior to newborn hearing screening. A recent study demonstrated that for infants screened for hearing loss compared to those unscreened there was a 24.8-month difference in median age at diagnosis of hearing loss, a 23.6-month difference for fitting of amplification, and a 19.9-month difference for enrollment in intervention (16).

Early hearing loss detection and intervention has been a goal for almost 40 years. Previously, risk factor screening was the only means available to try to identify infants with hearing loss. A 1972 statement by the Joint Committee on Infant Hearing (JCIH) (17) delineated the first high-risk factors for hearing loss and recommended following infants with these high-risk factors: history of hereditary childhood hearing impairment; congenital infection acquired *in utero*, such as rubella or other nonbacterial fetal infection like cytomegalovirus (CMV), syphilis, and herpes; craniofacial anomalies including those with morphologic abnormalities of the pinna and ear canal; birth weight less than 1,500 g; and a bilirubin level greater than 20. In 1982, bacterial meningitis and severe asphyxia were included with

additional risk indicators added between 1982 and 1994. Although this list was expanded and the name changed to risk indicators, risk indicator screening identified only 50% of infants with significant hearing loss.

Because hearing loss affects a large number of children and risk indicator screening is ineffective, and age of identification and habilitation of hearing loss is important, the National Institutes of Health's (NIH) Consensus Development Conference on Early Identification of Hearing Loss (18) concluded that all infants should be screened for hearing impairment, preferably prior to hospital discharge. The following year, JCIH endorsed the goal of universal detection of hearing loss in infants and recommended that physiologic tests be used. The JCIH (19) position statement became a comprehensive guide for early hearing loss detection and intervention for hearing loss and was subsequently revised in 2007. Some of the changes in the 2007 position statement were the expansion in the definition of hearing loss to include auditory neuropathy/dyssynchrony for infants admitted to the neonatal intensive care unit (NICU). Prior to this, the definition included only permanent bilateral, unilateral sensory, or permanent conductive hearing loss. The 2007 position statement also included separate protocols for NICU and regular-care nurseries to address neural hearing loss that occurs more commonly in the NICU. Infants in the NICU for more than 5 days are to have auditory brainstem response (ABR) included as part of their screening so that neural hearing loss will not be missed. For NICU infants who do not pass the ABR, the recommendation is that they are referred directly to an audiologist for rescreening and/or comprehensive evaluation including ABR testing. In addition, if any infant is readmitted during the first month of life for conditions associated with potential hearing loss (e.g., hyperbilirubinemia that requires exchange transfusion or culture-positive sepsis), a repeat hearing screening is recommended before discharge.

The 2007 Position Statement by JCIH (9) also recommended that all newborns be screened for hearing loss by 1 month of age. If the child fails the screening process, an audiologic diagnostic evaluation should occur before 3 months of age, and when a hearing loss is confirmed, the child should be enrolled in early intervention before 6 months of age. These guidelines, commonly referred to as the 1-3-6 model, have been widely adopted by such organizations as NIH/NIDCD, Health Resources and Services Administration/Maternal and Child Health Bureau, American Speech-Language Hearing Association (ASHA), American Academy of Audiology (AAA), and American Academy of Pediatrics (AAP). The JCIH 2007 (9) also contains a section on the role of otolaryngologist in the care and evaluation of newly diagnosed hearing losses in infants.

Because hearing loss can occur after the child leaves the hospital, the JCIH also recommends that periodic audiologic examination of infants be conducted to detect delayed-onset hearing loss. Children with indicators of progressive or delayed-onset hearing loss should be referred for an audiologic assessment at least once by 24 to 30 months of age. Children with risk indicators that are highly associated with delayed-onset hearing loss, such as having received extracorporeal membrane oxygenation (ECMO) or having CMV infection, should have more frequent audiologic assessments.

JCIH risk indicators that are associated with progressive or delayed onset of hearing loss in childhood are listed in Table 100.1.

TABLE 100.1 JCIH RISK INDICATORS ASSOCIATED WITH PROGRESSIVE OR DELAYED ONSET OF HEARING LOSS IN CHILDHOOD

1. Caregiver concern regarding hearing, speech, language, or developmental delay.*
2. Family history of permanent childhood hearing loss.*
3. Neonatal intensive care of more than 5 d or any of the following regardless of length of stay: ECMO*, assisted ventilation, exposure to ototoxic medications (gentamicin and tobramycin) or loop diuretics (furosemide), and hyperbilirubinemia that requires exchange transfusion.
4. *In utero* infections, such as CMV*, herpes, rubella, syphilis, and toxoplasmosis.
5. Craniofacial anomalies, including those that involve the pinna, ear canal, ear tags, ear pits, and temporal bone anomalies.
6. Physical findings, such as white forelock, that are associated with a syndrome known to include a sensorineural or permanent conductive hearing loss.
7. Syndromes associated with hearing loss or progressive or late-onset hearing loss*, such as neurofibromatosis, osteopetrosis, and Usher syndrome; other frequently identified syndromes include Waardenburg, Alport, Pendred, and Jervell and Lange-Nielson.
8. Neurodegenerative disorders*, such as Hunter syndrome, or sensory motor neuropathies, such as Friedreich ataxia and Charcot-Marie-Tooth syndrome.
9. Culture-positive postnatal infections associated with sensorineural hearing loss*, including confirmed bacterial and viral (especially herpes viruses and varicella) meningitis.
10. Head trauma, especially basal skull/temporal bone fracture that requires hospitalization.*
11. *Chemotherapy

Note: Risk indicators that are marked with a "*" are of greater concern for delayed-onset hearing loss.

SCREENING BEYOND THE NEWBORN PERIOD

Given that hearing loss can occur at any time or be of a progressive nature, screening for hearing loss beyond the newborn period is important. In fact, screening for hearing loss in children and middle-ear disorders has been around for many years in schools, clinics, and health departments. Although there is this long history, variability in procedures remains. Routine hearing screening often starts with the preschool-age child who can perform developmentally appropriate pure-tone procedures. These screenings are conducted in daycares, preschools, and in some primary care physician offices. There is currently an initiative to capture the 0- to 3-year-old population who attend early head start programs using otoacoustic emissions (OAE) as the screening tool (20).

Hearing screening in the school-age population has had a variety of policies and procedures as not all states have legislative mandates, and policies can be written by individual school districts or health departments. The AAA (21) and the ASHA (22) recommend pure-tone screening at the child's initial entry into school, annually in kindergarten through third grade, seventh grade, and eleventh grade. Screening should be conducted at 20-dB HL for frequencies of 1,000, 2,000, and 4,000 Hz. Failure to respond at any frequency in either ear necessitates rescreening. Failure on rescreening requires a referral for audiologic evaluation within 1 month of rescreening and no later than 3 months after the initial screening.

Routine screening of middle-ear disease is not recommended as a stand-alone screening but may be done as part of a comprehensive hearing screening protocol in children who are at risk for otitis media (23). Because of the transient nature of middle-ear disease and resolution of the middle-ear disease without treatment, routine tympanometric screening can lead to too many children being referred to their physicians without middle-ear effusion at the time of the visit.

DEVELOPMENT OF AUDITORY BEHAVIOR

Although infants are born with the ability to hear, some developmental changes occur with respect to their perception of sound, and neural processing ability continues to develop well into childhood and adolescence. The auditory system is intact early and becomes functional during the third trimester at around 25 weeks gestation (24). The central pathway, however, continues to develop well into adolescence with increase in myelinization and neural pathway development. Brainstem myelinization is complete by 1 year of age but the central structures complete myelinization at 10 years or older. These changes can be reflected in evoked potentials that undergo changes in amplitude and latency of the responses, although not in threshold.

Early on in life, infant's responses to sounds are often of a reflexive nature until they develop the motor control for a more organized response. With increasing age, the intensity level of the auditory stimulus that is needed to elicit a response from the infant decreases. Beginning about 5 to 6 months of age, when formal audiologic techniques can be utilized, adult-like values can be obtained to auditory stimuli. These changes in response levels are not indicative of sensitivity differences but in the minimal stimulus level needed to elicit a response.

Infants begin to localize sounds first in horizontal and then vertical planes. Between 3 and 6 months of age, infants search for the sound, respond to the sound of their name, and respond differentially depending on the tone of voice the parent is using. By about 5 to 6 months, formal and reliable behavioral-audiologic testing can begin. Between 6 and 10 months, infants can seek out the source of sound and respond to common sounds in their environment. They respond to both loud and soft sounds and pay attention when the parent talks to them. Between 10 and 15 months of age, babbling increases and begins to more closely resemble speech. Between 15 to 18 months, a baby is able to directly localize to most sounds, understand simple phrases, identify familiar objects such as body parts, and follow simple directions. A child at 18 months should have an expressive vocabulary of 20 or more words and short phrases.

TEST BATTERY

For pediatric assessment, the cross-check principle, originally developed by Jerger and Hayes (25), is utilized. Use of the cross-check principle helps to minimize mistakes in diagnosis and develop an audiometric profile that best represents the child's auditory abilities. This principle relies on a combination of behavioral and physiologic tests to provide a comprehensive picture of hearing sensitivity and auditory status. Behavioral tests, although usually considered more subjective because of their reliance on patient participation, are combined with the results of objective physiologic tests that do not require active participation by the child/infant. At very young ages or in the case of significant developmental delay, the electrophysiologic test (e.g., ABR) findings often predominate in the initial decision making about the management of the child with a hearing loss. As the child develops and can participate in behavioral testing, the behavioral findings will serve as validation of electrophysiologic findings, as well as document sequential development of auditory skills. For older children with developmental skills adequate for behavioral testing, audiologic findings with or without ABR supporting data are used to determine management of the hearing loss.

The goal of behavioral audiologic assessment is to establish the degree and nature of any hearing loss for each ear so that management of hearing loss, including

hearing aid fitting, can be done. The evaluation includes a comprehensive history, observation of the child's awareness of or use of sound, as well as multiple tests to assess various aspects of the auditory system, including cursory otoscopic examination, tympanometry, assessment of acoustic reflexes (ARs), and behavioral audiometric testing (air conduction and bone conduction) to both speech- and frequency-specific stimuli.

SPECIAL TESTS

Auditory Brainstem Response Testing

For the very young child, physiologic assessment procedures using auditory evoked potentials, such as ABR, are particularly important. The ABR can be used for both identification and assessment of hearing and can provide accurate estimates of threshold sensitivity (26). Under good recording conditions, and using frequency-specific stimuli, the ABR can provide reliable estimates of sensitivity across the frequency range of hearing (27) in children of all ages. Although this is the test of choice in children under 6 months of age, the ABR is used for older children who cannot be tested behaviorally. Typical recommendations for the ABR include failure to obtain behavioral audiologic thresholds after two attempts, or a high suspicion that a hearing loss exists and that continued testing would only delay diagnosis.

The ABR follows neuromaturation of the central auditory nervous system and shows wave latency changes until about 18 months of age. Wave I is mature early on in life and show little if any latency change with age, whereas the later waves continue to decrease in latency with increase in age to about 18 months of age, with the most rapid changes occurring in the first 3 months after birth. The interwave latency difference between wave I and V therefore goes from about 5.0 at birth to about 4.0 milliseconds when mature. Thresholds do not change over time if hearing is stable. The ABR is best conducted while the infant is sleeping to eliminate background myogenic noise, which can overshadow the neural response. Young infants can often be tested during a natural sleep, following a feeding. Older infants may need to have sedation. ABR done under sedation is now more routinely done in procedure centers where there is a physician and nursing support for sedation monitoring throughout the test session.

The ABR may be used to estimate an audiogram, but some drawbacks exist. The major limitation is the choice of stimuli available that can be used to elicit a response. Synchronous neural firing of multiple neurons is essential to record a response. The best stimulus to elicit a response is a rapid or abrupt onset stimulus such as a click that stimulates a broad area of the basilar membrane and therefore generates synchronous neural discharge in a large number of neurons. The ABR to click stimuli will provide an overall assessment of the integrity of the auditory pathway and provide a basis on which to start investigating thresholds at specific frequencies.

The click stimulus, however, is not frequency specific but contains energy in a broad frequency range and responses obtained to click stimuli cannot detect frequency-specific impairment. The responses to click stimuli have been found to correlate best with audiometric findings in the higher frequency range from about 1,000 to 4,000 Hz frequency range (28–32). Use of this stimulus solely can either underestimate or miss a hearing loss at a particular frequency or frequencies depending on the degree and configuration of the hearing loss (33,34). While the use of age-appropriate latency-intensity functions together with the threshold search will help to identify impairments, exact quantification of the impairment at each frequency cannot be done using the click stimulus. Rather more frequency specific or tonal stimuli need to be used.

The stimulus that is commonly used to obtain frequency-specific information is a brief duration tone burst referred to as a tone pip. With the use of this stimulus, fairly good synchronous neural firing can occur. The trade off in becoming frequency specific or tonal by increasing the rise time of the stimulus is the reduction in the synchronous neural discharge. The aim is to achieve a balance of tonality with enough synchronous neural firing to elicit a response. It is necessary to maintain a fast enough rise time to elicit a response yet reduce the acoustic splatter to frequencies above and below the nominal frequency of the stimulus. While producing a stimulus that does not have contributions from other frequencies is important, it will not ensure a place-specific region of excitation on the basilar membrane. Physiologically there is an upward spread of excitation on the basilar membrane as the intensity level of the stimulus is increased beyond 70-dB sound pressure level (SPL) (35). Spread of energy to frequencies with better hearing will result in an underestimation of threshold level. For children with severe to profound hearing losses, the intensity level of the stimulus will be sufficiently high that there is to be expected some spread of energy on the basilar membrane.

ABRs should be obtained to both air and bone conducted stimuli and thus can provide information about type of hearing loss. Bone conduction should be elicited to at least a click stimulus to assess presence or absence of air-bone gaps. While there are intensity output limitations in bone conduction testing, such testing often confirms the type of auditory impairment. Threshold differences of greater than 15 dB with better bone conduction thresholds than air conduction thresholds are indicative of conductive involvement and warrant further otologic evaluation.

The ABR measures the integrity of a portion of the auditory system through approximately the level of the midbrain and does not measure "hearing" in the true sense of the word. Although it is well established that agreement exists between behavioral thresholds and ABR thresholds for children with typical sensory hearing loss, there

are instances where they will not agree and further investigation is necessary. Examples include cases of normal ABR with no ability to recognize or use sound to "hear." Conversely, the absence of an identifiable waveform on an ABR test does not necessarily equate to thresholds in the severe to profound range or to "no hearing." The limits of the ABR equipment should be recognized. Output is more limited than most audiometers used to test behaviorally. Consequently, an absent response on ABR should not be interpreted as the absence of residual hearing. Additionally, the ABR will be affected by the neurologic status of the child. If the auditory system is damaged and neurons cannot fire synchronously, or if there are disruptions of the auditory pathway due to an insult, then the integrity of the ABR may be compromised resulting in no identifiable ABR waveform or a partial waveform with later waves absent, despite the fact that the end organ of hearing, the cochlea, may be functioning normally. With the availability of technology to monitor OAE from the cochlea, discrepancies between behavioral audiologic findings and the ABR, where behavioral audiologic findings show better responsivity to sound than can be predicted by the ABR, are being substantiated by the presence of OAEs. These hearing losses are either auditory neuropathy or neural hearing loss. Auditory neuropathy represents good outer hair cell function but a disruption in the peripheral nerve, whereas neural hearing loss is a breakdown in nerve transmission that occurs more centrally.

Auditory Neuropathy Spectrum Disorder is a term that found more and more frequently in the literature and is being used indiscriminately in cases where OAEs are present and the ABR is absent or abnormal. Rapin and Gravel (36,37) delineate clearly the distinction between neural, sensory, sensorineural, central hearing losses, and auditory neuropathy. They point out that neuropathy means that there is peripheral nerve pathology, yet much of the literature contains cases where this was not shown. For example, neonates with hyperbilirubinemia and resulting hearing losses show abnormal ABRs and normal OAEs, yet the primary site of pathology is the central auditory pathway, that is, vestibular and cochlear nuclei and basal ganglia and not the VIII nerve, yet it is often said that hyperbilirubinemia is a risk factor for auditory neuropathy. Combining all children with abnormal ABRs and present OAEs into one category will present challenges for managing the hearing losses effectively. Furthermore, until there is clearer differentiation, we will be unable to help families understand their child's hearing loss and expected outcomes. This is clearly an area where the audiologist and otolaryngologist need to work closely together to ensure proper diagnosis of hearing loss.

An emerging physiologic evoked potential test, the auditory steady-state response (ASSR), holds promise for predicting frequency-specific thresholds in individuals who cannot provide reliable or valid behavioral thresholds, for example, in young infants and children (38–41). The advantage of this measure is that it is truly an objective measure because the response presence or absence is based on statistical analysis and not on visual detection methods as with the ABR.

The generation of the 80-Hz ASSR, like the ABR, is believed to be primarily in the brainstem (42). ASSR uses relatively tonal stimuli (carriers) that are amplitude- and/or frequency-modulated to evoke a response and can provide accurate frequency-specific estimates of air conduction hearing levels. For pediatric applications, the modulation occurs at a frequency appropriate for infants and children (about 80 to 100 Hz). Single or multiple stimuli presented simultaneously have been used to elicit the ASSR (43). Furthermore, the 80 Hz ASSR can be obtained in infants and young children who are asleep (44). The test has the ability to monitor both ears simultaneously, making it attractive for possible reduction in test time compared to the ABR, although more research is needed in this area before conclusions can be drawn as to whether there is truly a time savings. Threshold prediction using the ASSR conducted on adults and children with hearing loss has been shown to provide fairly accurate estimates of the behavioral audiogram (41,45–51).

Hearing thresholds have been estimated within about 10 to 15 dB in adults with normal hearing and hearing loss using the multifrequency ASSR (39,52). Fewer data, however, exist regarding the use of the ASSR for measurement of hearing in infants and children. Perez-Abalo et al. (53) found that although they were able to determine hearing loss in the severe and profound range, only fair agreement was seen between ASSR thresholds and hearing levels in children with mild hearing loss or normal hearing.

Few data exist regarding the use of ASSR employing bone conduction stimulation. Small and Stapells (54) used multiple bone conduction stimuli that were both frequency and amplitude modulated in a group of preterm infants (32 to 43 weeks) and a group of full term infants (0 to 8 months). The results obtained in infants were different from those obtained in adults; in infants, the threshold estimates were better in the lower frequencies and poorer in the higher frequencies when compared to adult data. Swanepoel et al. (55) evaluated bone conduction stimulation in a group of older children and concluded that the stimulus artifact prevents determination of type of hearing loss in most cases of sensorineural hearing loss but interferes less when conductive hearing losses are present. However, results vary with frequency in both cases.

The influence of age on the ASSR suggests that maturation has some bearing on threshold determination in very young infants. Rance and Rickards (56) found that the prediction of hearing thresholds was similar between young (1 to 8 months of age) infants and older subjects with hearing loss. However, results obtained from infants with normal hearing have suggested that maturational factors, which are sufficient to affect the differentiation

between normal hearing and mild-to-moderate hearing loss, may influence the findings of ASSR assessments carried out in the first few weeks of life (38,47,57–60). Recently, Rance and Tomlin (61) evaluated neonates and young infants with normal hearing and found their ASSR threshold levels were different from those observed in older subjects. They concluded that when the ASSR is used clinically, it is necessary to take into account developmental changes occurring in the first weeks of life. Furthermore, their findings indicated that ASSR thresholds in normal-hearing babies at 6 weeks of age were not yet mature. Clearly, this is a tool that has much promise for assessment of infants and young children, but further research and refinement are needed in all aspects of the ASSR to determine if it will produce accurate audiogram predictions in all infants.

Otoacoustic Emission Testing

The test that helped to propel newborn hearing screening into the standard of care for all newborns are OAEs. OAEs are sounds that originate from physiologic activity inside the cochlea and that can be recorded in the ear canal. The literature is rich with evidence that this activity is associated with normal to near normal hearing processes (62,63).

The sensory, or outer hair cells, within the organ of Corti are thought to be responsible for the generation of OAEs, specifically the electromotility of the outer hair cells (64). Thus, the OAEs give us the ability to view the functioning of the cochlea, although not without contribution of the middle ear. That is, the sounds created in the cochlea are passed through the middle ear via the ossicular chain and eardrum. These sounds are then recorded by placing a microphone in the ear canal. Consequently, healthy middle ears that can transmit sound to and from the cochlea effectively are essential to being able to record the OAEs.

OAEs are classified according to whether there is a stimulus used to record them. Spontaneous Otoacoustic Emissions are recorded when no stimulus is present and Evoked Otoacoustic Emissions (EOAEs) are recorded following a stimulus. The two clinically useful EOAEs are Transient Evoked Otoacoustic Emissions (TEOAEs), which are recorded following a brief acoustic stimulus (click), and Distortion Product Otoacoustic Emissions (DPOAEs), which are recorded following two simultaneously presented pure tones.

The click, as it does in the ABR, produces a broadband stimulus and therefore a response from a wide range of frequencies. While the click stimulus used to elicit the response is not frequency specific, TEOAEs, unlike the ABR to click stimuli can be analyzed in frequency bands to provide information that is frequency specific. The stimulus level of 80 to 84 dB SPL is used to elicit TEOAEs because this level is optimal for obtaining a response. The response amplitude is recorded over a 20-millisecond time window following the stimulus. The higher frequencies are recorded in time first because they originate closer to the base of the cochlea and have shorter latencies. The lower frequencies come from more apical portions of the cochlea and consequently have longer latencies and are recorded next. Presence or absence of a response is determined by evaluating the response amplitude relative to the noise floor and the response reproducibility of the waveform (two waveforms are generated for each test), assuming that the stimulus is maintained at a proper intensity level. In general, the TEOAEs response amplitude is higher in children than in adults, many times making it easier to obtain a response from a young child.

DPOAEs are recorded following the simultaneous presentation of two pure tones that are related in frequency. The interaction of the tones produces a third tone emitted from the cochlea, not present in the original stimuli. Distortion products are by-products of a normal nonlinear system, in this case the outer hair cells. DPOAEs allow for more frequency-specific stimulation of the cochlea as compared to the click stimuli used to elicit TEOAEs. The intensity level of the two stimuli is either equal or the lower frequency stimulus has a higher intensity by approximately 10 to 15 dB. DPOAEs are plotted on a DP gram with DPOAEs response amplitude as a function of frequency. Absolute amplitude of the response or amplitude relative to the noise level determines presence or absence of a response. Like TEOAEs, the amplitude of DPOAEs is larger in children than in adults.

Recording OAEs allows measurement of cochlear function objectively and noninvasively. OAEs are generated exclusively by outer hair cells. Most hearing losses do not involve inner hair cell damage without outer hair cell damage; that is, outer hair cells are generally more vulnerable to disease and damage than inner hair cells. Therefore, the presence of an emission provides us with reasonable assurance that hearing thresholds are 30 to 40 dB or better in the frequency range where the emission is present. OAEs may be absent due to middle-ear dysfunction, resulting in inability of the emission to be transmitted, or to sensory hearing loss affecting production of the emission. Prediction of hearing levels is not possible by measuring OAE. The absence of OAE can be associated with hearing loss of mild to moderate degree and greater, and their presence does not ensure normal hearing. When measuring OAEs in young children, their amplitude may be reduced in the low-frequency regions (1,000 Hz and below) because of interference from the low-frequency physiologic and ambient noise in this region. Consequently, absent OAEs in low-frequency regions alone are insufficient for determining presence or absence of hearing loss. OAEs should constitute one test in a battery of tests for accurate interpretation. OAEs are sensitive to hearing losses and can be absent with as little as a 20 to 30 dB HL hearing loss. The absence of OAEs must be viewed within the context of the status of

the middle ear, since both the stimulus and the response pass through the middle ear. Therefore, the absence of an OAE is diagnostically significant for sensorineural hearing loss only when middle-ear function is relatively normal.

Immittance Testing

Other tests that are important to the test battery used for the audiologic assessment of infants and young children are acoustic immittance tests of tympanometry, equivalent ear canal volume, and AR threshold monitoring. These tests are especially important when one considers the high incidence of otitis media with effusion (OME) in young children. Acoustic immittance testing serves to differentiate and/or substantiate other test findings. Tympanometry, an indicator of tympanic membrane mobility and middle-ear pressure, is used to infer middle-ear function. Tympanometry assesses the movement of the tympanic membrane in response to mechanically varied air pressure and indirectly measures tympanic membrane mobility by measuring the amount of reflected sound, or inversely by the amount of sound passing through the tympanic membrane to the middle ear. Standard tympanometry uses a low-frequency probe tone of 220 or 226 Hz for measurement. However, the interpretation of the tympanogram and AR findings may be compromised when this probe tone is used with infants less than 4 months of age. Specifically, findings in the ears of infants with middle-ear fluid show normal-appearing tympanograms (65). The most likely explanation for this false reading is related to the fact that mass and stiffness contributions are different between adults and children—children have a more mass dominated system as compared to an adult stiffness dominated system at low frequencies. Therefore, the use of a higher probe frequency (e.g., 1,000 Hz) is recommended in order to obtain tympanograms that are a more valid indication of middle-ear function for infants aged 6 months or less (66–72).

Tympanometry using a high-frequency probe tone cannot be interpreted in the same manner as those tympanograms that were obtained with a 226 Hz probe tone. The volume readings are higher and only volume readings from 226 Hz should be used or erroneous diagnosis can be made. Furthermore, there are no established large-scale normative values available at this time as the shape of the tympanogram can vary widely from those obtained with a standard 226 Hz probe tone.

With a flat tympanogram, equivalent volume measurements may provide information of probe tip occlusion, intactness of the tympanic membrane, and tympanostomy tube patency. A very small volume may indicate probe tip occlusion or external auditory canal stenosis or blockage. A large volume may indicate a tympanic membrane perforation or open tympanostomy tube. The equivalent ear canal volume varies with age as infants may be approximately 0.3 mL (73), children aged 3 to 5 years are 0.7 mL and adults are 1.1 mL.

AR testing monitors stapedius muscle response to loud sound, which indicates middle ear and auditory brainstem activation. The AR can be a very useful part of the audiologic evaluation in infants. A present reflex is added support for normal middle-ear function, as well as information about the integrity of a portion of the auditory brainstem pathway. These tests are both objective measures but abnormal acoustic immittance findings and/or the presence of fluid does not determine hearing levels. Furthermore, the tests used for assessment of hearing do not determine the presence of fluid. Therefore, acoustic immittance measures in combination with hearing assessment measures help to provide a complete picture of the status of the Ear Hear and can help the examiner to make proper recommendations.

Wideband energy reflectance, wideband impedance or generally defined as wideband acoustic immittance, is a relatively new method of assessing middle ears of infants and children. Wideband reflectance research is emerging with some supporting literature that it offers improved diagnosis of middle-ear conditions compared to single-frequency tympanometry (74–76).

Pure-Tone Testing

The reliance on physiologic measures shifts to behavioral measures typically around the developmental age of 6 months. As with physiologic testing, the goal of the behavioral test battery is to obtain ear- and frequency-specific thresholds to both air and bone conducted stimulation. Similar to adults testing, behavioral testing of infants is conducted in a sound-treated room, but for children the booth needs to be larger in size than those used for adults. Behavioral response levels can be obtained using Behavior Observation Audiometry (BOA), visual reinforcement audiometry (VRA), play audiometry, and conventional audiometry for the older child.

Behavioral Observation Audiometry

For infants from birth up to 5 or 6 months of age, behavioral assessment is limited to this technique of observing response changes (e.g., cessation of sucking, eye movement, and startle) to auditory stimuli. Since infant responses will occur at levels above threshold and are quite variable, BOA cannot be used to assess threshold. For the very young infant, reliance on physiologic measures for threshold estimation is necessary. BOA is important, however, for understanding infant's responses to sounds and can be beneficial for families and clinicians to understand the infant's auditory development.

Visual Reinforcement Audiometry

For children developmentally 5 to 6 months of age, it is possible to use a conditioned auditory response, called

VRA, to measure hearing threshold levels. This is an operant conditioning paradigm that reinforces a motor activity, usually a head turn, with an appealing visual display, usually a lighted, animated toy or simple video display (Fig. 100.1). The auditory signal or stimulus cues the infant that a response, that is, head turn, will result in reinforcement. Studies have shown that frequency-specific thresholds can be obtained from infants at developmental levels of 5 to 6 months, producing accurate measures of hearing sensitivity (77–83).

VRA can be conducted using insert earphones (the transducer of choice), for ear-specific responses, and a bone conduction vibrator. If the child will not tolerate the use of earphones, results can be obtained using stimuli presented via sound field (presentation via speakers) into the test booth or sound isolating room.

Conditioned Play Audiometry

As children get to be about 2 years of age, they can usually perform testing using a play task, called play audiometry. The child is conditioned to respond to pure tones by playing a simple game using toys such as stacking rings, peg boards or simple puzzles or a combination of play activities to maintain interest. Standard testing techniques are used and thresholds obtained using play audiometry in a cooperative child is assumed to be adult-like.

Conventional Behavioral Audiometry

Conventional behavioral audiometry can be conducted using a hand raise response and can be done starting at developmental age of 5 years. When testing children, however, testing methods may need to change in order to maintain interest and participation of the child patient. Flexibility is key to maximizing obtaining needed information to diagnose a child with a hearing loss.

As with adult testing, speech testing (word recognition testing) is a component of the evaluation but is typically not done until the child has sufficient language proficiency to participate for the testing. This is typically around developmental age of 3 to 4 years. Like behavioral testing, adaptations are made to ensure that the child is capable of participating in the task and their attention can be maintained. Thus speech testing often begins with a picture pointing test such as the Northwestern University Children's Perception of Speech, Word Intelligibility by Picture Identification (WIPI), or Pediatric Sentence Identification test.

In addition to conductive, sensorineural, mixed hearing loss, and neural hearing losses, children with processing disorders need to be identified. Auditory processing involves not only the perception of sounds but interpretation and understanding of sound, even in less than optimal conditions. Children can present, therefore, with normal hearing sensitivity yet may not be able to follow directions well or understand complex sounds, especially in difficult listening situations, such as a noisy classroom. Clinical features of auditory processing disorders (APDs) include: (a) easy distractibility, (b) delayed responses, (c) difficulty following directions, and (d) unexplained behavioral problems. Children need to have normal cognitive function and the ability to cooperate for a battery of tests in order to be evaluated for APDs. There are no standard protocols for such testing, and each clinician develops their own protocol. Furthermore, there is no gold standard against which to evaluate the diagnostic tools that are used and there is lack of data on the rehabilitation protocols. Regardless of these issues, there is agreement that the problem does exist and this is an area that falls within the scope of practice of the audiologist (84). Management of APD involves (a) improving the listening environment in the classroom with preferential seating or an frequency modulated (FM) system, (b) utilizing compensatory strategies such as repetition or cueing, and (c) therapy to improve auditory skills such as memory or perceptual training.

Figure 100.1 VRA. An 10-month-old infant is conditioned to turn his head to a video display when an auditory stimulus is detected.

Degree of Hearing Loss

For children, the classification of degree of hearing loss is often more stringent, as hearing loss in this population can significantly affect the development of speech and language and can have negative educational impacts, if left undetected. At average conversational levels, the unvoiced consonants: *s*, *p*, *k*, *th*, *f*, and *sh* fall at or below normal adult hearing levels, so better hearing is needed for more-consistent detection of these sounds. This is the reason for setting the critical range of hearing at 0 to 15 dB for a young child. The ASHA classifies hearing loss as tabulated in Table 100.2.

REVIEWING TEST RESULTS

The pediatric audiologic evaluation, in comparison to the adult evaluation where hearing loss can be defined in one clinic visit, often requires repeated visits scheduled in close proximity before the exact configuration and degree and sometimes nature of the hearing loss is defined. The audiologic assessment of children, but in particular, for the very young infant with a hearing loss is a time-intensive and an on-going process. While a comprehensive audiometric profile is always the goal and necessary before the hearing aid fitting process can be completed, reliable estimates at critical frequencies can be used to initiate the amplification and habilitation process, with refinements and adjustments of the hearing aid fitting occurring as more and more precise information is obtained. Delays in habilitation are not acceptable even when only partial information is available, and valuable time should not be wasted waiting for complete information.

TABLE 100.2 HEARING LOSS CLASSIFICATION

Degree	Hearing Level (dB)	Impact on Child
Normal	0–15	Child will hear all speech sounds
Slight	16–25	Child will hear vowel sounds clearly, but might miss some consonant sounds
Mild	26–40	Child will hear only some of the speech sounds
Moderate	41–55	Child will hear almost no speech sounds at a normal speaking level
Moderate to severe	57–70	Child will hear no speech sounds at a normal speaking level
Severe	71–90	Child will hear no speech and almost no other sounds
Severe to profound	>90	Child will hear only few other sounds

MANAGEMENT OF HEARING LOSS

Management of hearing loss in children starts first with counseling the family about the hearing loss, supporting their emotional needs as they deal with the diagnosis, helping them to understand the modes of communication available, finding opportunities for financial support for hearing aids, then moving onto fitting of amplification, and enrollment into an educational program, such as early intervention, geared to helping develop communication for those with hearing loss. The majority of families of children with hearing loss opt to provide amplification for their child (Compiled by the NIDCD).

In those instances where there are family members with hearing loss, careful exploration of the family's wishes needs to occur to ensure that they are respected in their beliefs, while also trying to achieve accuracy in their understanding of the hearing loss and what options are now available for their child. While the hearing aid fitting process is beginning, referral to and enrollment into an early intervention program is a must so that the families have the educational help and support that they need on an ongoing basis.

THE ROLE OF THE OTOLARYNGOLOGIST IN THE ASSESSMENT AND REHABILITATION

The otolaryngologist has the primary responsibility to assess for the etiology of the hearing loss. History may reveal risk factors for hearing loss such as perinatal events, ototoxin exposures, head trauma, or family history of early onset hearing loss. Physical exam may identify stigmata of syndromes. Further evaluation may involve genetic testing, radiographic imaging, ophthalmologic referral, and other indicated laboratory tests.

The otolaryngologist also provides medical clearance for hearing aids. The United States Food and Drug Administration requires that clearance occurs within 6 months of the fitting of hearing aids in children less than 18 years. The otolaryngologist works in close conjunction with the audiologist and monitors for progressive change in hearing and discusses when other options, such as cochlear implants, are indicated. Routine exams also are required to monitor for factors (e.g., excessive cerumen, earmold size) that may interfere with hearing aid fitting.

Hearing Aid Fitting

The goal of amplification is to make speech audible, which is often the primary mode of communication chosen by parents as most hearing losses in children occur in families who hear. Children learn spoken communication skills from hearing the sounds around them and the ability to hear consonant sounds carries with it

information critical to understanding the spoken message. The most common form of amplification is a personal hearing aid for these children, and as they grow, other assistive technology may be added and include such things as FM systems or implantable devices such as cochlear implants.

Advances in technology have helped with better outcomes for children with hearing loss. In general, the hearing aids have become smaller and stay on small ears better, have more options, and have better strategies to enhance speech in the background of noise. Research on adults has shown that the newer technology appears beneficial. Little research has been done on children to prove that these same technologies are of benefit to them. Several reasons why this has not been done is that it is hard to measure benefit for children who are prelingual and it is hard to control for all factors that can affect outcome. New technology has been designed for people who have hearing loss in the high frequencies, a range where traditional hearing aids have not been able to amplify well. This technology is designed to give access to the higher frequency sounds by either compressing the frequency range to be within a person's range of hearing, that is, low- and mid-frequency range or moving the higher frequency sounds to regions of better hearing. These technologies are referred to as frequency compression and frequency transposition, respectively. Older children have shown that they can receive benefit, but little is known about speech and language development in the prelingual child with a high-frequency hearing loss using these technologies. More research using these and other technologies are needed in the pediatric population.

Hearing aid fitting starts with having sufficient frequency-specific information to fit the hearing aid. The use of click data from the ABR is insufficient to fit a hearing aid, and thresholds from at least 500, 1,000, 2,000, and 4,000 Hz are needed. The hearing aid fitting is refined as more complete auditory information is obtained as the child grows. The child's ear, which is smaller in nature and has different resonances, alters the output of the hearing aid differently than when it is fit in an adult size ear. Standard measurement of output of a hearing aid is closer to what an adult may hear but only measurement of the amplified sound in the ear can verify the actual sound reaching the ear drum. The bony portion of the external auditory canal alters size through 7 years of age, and the pinna grows until approximately 9 years of age. The primary postnatal change in the middle ear is a positional change of the tympanic membrane and ossification of the bones in the middle ear. These changes that continue to occur in childhood affect the output of the hearing aid as measured in the ear canal of the child. Consequently, there is a need to account for the child's ear canal acoustics.

In general, the smaller the ear relative to the adult ear results in a higher intensity of sound in the young child's ear, and this can vary by upwards to 15 dB, resulting in uncomfortable or even damaging levels in the young child's ear. Since there is great variability among ears in ear canal acoustics, it is imperative that measurements be made in the ear using real-ear measurement systems. For young children, this can be a challenge, as the patient needs to remain still and not vocalize during these measurements. An alternative approach is to use the real-ear to coupler difference (RECD) measure to determine the acoustic response in an occluded ear canal without repetitive real ear measures. The RECD is calculated by first determining the SPL using the child's earmold seated in the child's ear (or a standard ear tip) that is coupled to an insert earphone transducer. A second SPL measure is made and that is of the 2 mL coupler. The RECD is the difference between these two measures or the difference between the SPL across the frequency range of the signal from the insert earphones transducer measured in the ear and the SPL of the same signal measured in the 2 mL coupler. This measure is then added to the hearing aid output measured in the 2 mL coupler to estimate the amount of amplification being delivered to that child's ear. Average values are available but not recommended as there is wide range of variability in the RECD measure among children of the same age. The hearing aid gain is adjusted following a prescriptive formula such as the Desired Sensation Level Multistage Input/Output Algorithm (DSL m[i/o]) v 5.0a as it was developed specifically for use with children. Verifying that targets have been reached is a critical step in the hearing aid fitting process and again, with children, since real-ear measures most likely will not be able to get completed successfully, the RECD is used to accurately predict real-ear measurements. The RECD is also used to help during the hearing aid fitting process to convert the dB HL thresholds to dB SPL, the measurement used for hearing aid output. The RECD needs to be remeasured with growth of the ear and is usually done with every earmold change. During the very early months in life, earmold changes occur about every 2 to 3 months and slows to about every 6 months after about 18 months of age. New RECD values dictate altering the hearing aid output to ensure proper amplification received by the child. The hearing aid process, like the diagnostic evaluation and counseling, is ongoing throughout the child's life as their needs change.

Today's digital hearing-aid technology provides a wide selection of amplification options and flexibility for optimizing gain, frequency response, and resulting speech audibility. For children, this flexibility is critical to ensuring optimal amplification. The behind-the-ear style hearing aid is the most widely used for the young children due to its greater flexibility in fitting of all degrees of hearing loss, durability, and less expensive option of replacing only the earmold as the ear grows compared to having to recase an in-the-ear (ITE) style hearing aid. ITEs may be appropriate when the child is older. The disadvantage is that they cannot be used with some hearing assistive technology that is used in classrooms, for example, FM systems. The

benefits of binaural amplification are well documented, for example, for sound localization and better ability to discriminate what is said in noise. Thus, binaural hearing aids are fit whenever residual hearing is apparent or until continued testing proves this to be detrimental or of no measurable benefit.

Because hearing aids amplify all sounds, noise is amplified along with speech. In the classroom, children with hearing loss often struggle to hear the teachers due to the high levels of background noise found in classrooms. The ability to hear and understand verbal information is important for learning. FM systems are a commonly used hearing assistive technology that allows the child (or anyone using this technology) to hear verbal information (speech) clearly. A microphone is worn close to the teacher's mouth and the speech signal is sent to the child's hearing aid, thus creating a situation that is like having the speaker close to the child's ear. The FM system uses radio transmission to send the signal from the microphones to a small receiver worn by the listener. This receiver is now often built into or attaches onto the hearing aids. While FMs are more commonly used in classrooms, they can be used in the home environment as well. FMs can also use speakers that can be portable or mounted in the classroom, thus potentially benefiting all children in the classroom. In addition to FM, other assistive technology such as induction loop and infrared systems are used and can be found in public settings such as theaters. Nowadays, Bluetooth is being used to connect to electronic devices such as cell phones and MP3 players.

Implantable Hearing Devices

Discussion of cochlear implants and implantable hearing devices is in Chapter 163. This section highlights the aspects unique to the pediatric population.

Implant Evaluation

Cochlear implantation is considered when conventional hearing aids are insufficient to provide the adequate auditory input for appropriate speech and language development. In pediatric populations, multidisciplinary evaluation helps determine candidacy. Otolaryngologists, audiologists, speech and language pathologists, psychologists, and social workers collaborate to assess infants and children prior to cochlear implantation. The preoperative speech and language evaluation determines whether developmental language or articulation disorders are present, defines the child's current communication abilities, and develops expectations and plans for speech therapy after implantation. The psychological evaluation assesses the intelligence and may identify cognitive disabilities that could affect a child's performance with a cochlear implant. As younger age children are receiving implants, families are counseled that some conditions such as autism and attention deficit disorders may not be evident until the child reaches 2 years of age. These evaluations are essential to establish appropriate expectations for parents prior to a cochlear implant. Current FDA guideline based on age for cochlear implants are in Table 100.3.

TABLE 100.3 PEDIATRIC COCHLEAR IMPLANT CANDIDACY

Ages 12 to 24 mo
Bilateral profound hearing loss
Lack of auditory skills development
Minimal benefit from hearing aid
No medical contraindication
Ages 24 mo to 18 y
Bilateral severe-to-profound hearing loss
Lack of auditory skills development
Minimal hearing aid benefit
No medical contraindications

In infants, speech perception tasks are not readily attainable and decisions about implant depend on electrophysiologic measures and detection thresholds. Most children will have an ABR as a component of the assessment. Unaided and aided threshold measurements corroborate ABR results and determine implant candidacy. Speech perception testing in children depends on their language abilities. The Meaningful Auditory Integration scale is a questionnaire for parents to assess the infant's response to sounds at home. Young children may participate in some closed-set measures such as objects or pictures (e.g., Early speech perception or WIPI). Open-set testing refers to tests when answer choices are not provided and may be performed in older children. Testing in children often involves the use of a 50 word list, the Lexical Neighborhood Test. For those children with vocabulary of a 5-year-old, the Phonetically Balanced Kindergarten test is used. For children with previous language acquisition, the Hearing in noise Test—Children may be utilized.

Early Implantation

Because of newborn hearing screen, children with hearing loss are being identified at an earlier age. The shift to an earlier age of implant is possible and questions about implants under the 12 months of age are raised. Evidence for the benefits of early implants was already demonstrated in those who were less than 24 months when they received an implant. These children had better perception and oral language scores than those who were implanted after 24 months of age (85,86). Even in children implanted at 12 to 18 months had overall better communication behaviors compared to those implant 19 to 36 months (87).

Evidence also supports that children implanted less than 12 months have even further benefits when compared to those who were implanted between 12 and 24 months (88–91). These studies demonstrate that language trajectories of infants implanted prior to 12 months old exceed that of children implanted after 12 months of age.

The surgical and anesthetic safety of infant implantation has been reported (92–94). Anatomically, infants are candidates as the cochlea is adult size at the time of birth. The surgical considerations in implanting infants and young children are that the physician has to be aware of blood loss. The mastoid also may be less pneumatized and more vascular because of the marrow and hemostasis has to be controlled meticulously, especially when bilateral simultaneous implantation is performed. Secondly, the skin flap over the device has to be maintained. Unlike in adults, in whom the skin flap has to be thinned on occasion to allow for the external magnet to adhere to the internal device, the surgeon has to be careful in maintaining the thickness of the flap over the device and minimize possibility of wound breakdown. Lastly, the skull thickness is less in younger children. This makes the likelihood of dural exposure greater in the infant when the bony seat or tie-down holes are drilled. Potential trauma to the dura or the surrounding vasculature has resulted in reported cerebrospinal fluid leaks, epidural and subdural hematomas, cerebral infarction, and lateral sinus thrombosis (95–98). Surgeons recently advocated not creating the bony seat to avoid these potential intracranial complications without device migration or flap issues (99,100).

The issues of bilateral cochlear implants are relevant in children as they are in adults. Bilateral implants provide the recipient improved hearing in noisy environments. This advantage is primarily from the head shadow effect with additional benefits from squelch and binaural summation (101). Sound localization is also improved with bilateral implants. This benefit is especially important in children in academic settings to track various speakers in classrooms. Moreover, these abilities provide children environmental safety to identify sources of sound such as when they cross streets.

Other benefits of bilateral implants in children is that since both ears have implants, the child will be assured to have one functional ear in case one of the implants, whether it is the internal receiver-stimulator or the external processor, malfunctions.

Performance with the implant is influenced by various factors including: age of implantation, duration of deafness, residual hearing, speech and language experience prior to surgery. Other factors that are relevant include higher ratings of parent–child interactions and higher socioeconomic status (102).

Otitis Media

Because the incidence of otitis media is higher in young children, the potential for OME or recurrent otitis media has to be addressed prior to and after implant surgery. Options for management of otitis prior to implant include prophylactic antibiotics, tympanostomy tubes, or mastoidectomy. The management of tympanostomy tubes at the time of implant surgery has been variable. A response to a survey of implant surgeons demonstrated that a majority proceeded with cochlear implantation with the tympanostomy tube in place. Others have advocated tube removal with myringoplasty at the time of cochlear implantation (103). Overall, a child who is a cochlear implant candidate with OME should have tympanostomy tubes placed. Cochlear implant then can be performed at a separate surgery. A child with a cochlear implant who has symptoms of otitis should be evaluated promptly and treated with antibiotics when otitis media is diagnosed. If the child develops recurrent otitis media then tympanostomy tubes may be considered.

Vaccination for Meningitis

Cochlear implants are associated with a small but present increased risk for meningitis. The incidence of streptococcal meningitis in cochlear implant patients is 0.14%. This number is a 30-fold increase compared to age-matched controls. Moreover, bacterial meningitis is higher in those who had an implant with a positioner or in those with radiographic evidence of an inner ear malformation (104). It is thus recommended that children with cochlear implants follow the recommendations for pneumococcal vaccinations. In February 2010, a 13 valent conjugate vaccine (Prevnar 13) was licensed by the FDA (105). It currently succeeds the previous 7 valent conjugate vaccine (Prevnar 7). Prevnar 13 contains polysaccharides of the capsular antigens of 13 serotypes of *Streptococcus pneumoniae*, conjugated to a nontoxic diphtheria carrier protein. The other vaccine currently in use is the 23 valent pneumococcal capsular polysaccharide vaccine (Pneumovax, PPV23). This vaccine contains pure capsular antigens from 23 serotypes. The conjugated 13 valent vaccine is necessary in infants and very young children because the immune system is immature to develop a response to pure antigens. More specifically, bacterial polysaccharides are T-independent antigens that stimulate mature B-lymphocytes but not T-lymphocytes. The very young respond poorly to T-independent antigens. Conjugation of bacterial polysaccharides to proteins changes the response to T-dependent and leads to substantial primary response among infants (106).

Key recent changes because of the PCV13 are:

Children less than 24 months, who have not received any previous dose of PCV7, should receive PCV13 as it is universally recommended.

Children 2nd through to their 6th birthdays should receive two doses of PCV13, if they have not received any doses of PCV7 or PCV13 previously. If they have already

completed the four-dose PCV7 series, they should receive one dose of PCV13 through age 71 months.

Children 6 through 18 years of age with cochlear implants may receive a single dose of PCV13, regardless of whether they received a PCV7 or Pneumovax.

Children older than 2 should also receive one dose of Pneumovax after completing all recommended doses of PCV13.

Bone Anchored Hearing Appliances

The primary indications for the bone-anchored device are for conductive hearing loss and for single-sided sensorineural hearing loss. In pediatric applications compared to adults, bone-anchored hearing appliances are more commonly indicated in those who have craniofacial malformations (e.g., bilateral aural atresia) that prevent a traditional hearing aid. Other indications include chronic ear conditions such as persistently draining ears, or patients with reactions to materials with molds or dermatologic external canal skin conditions.

The indication for a bone anchored hearing device for unilateral deafness has been increasing (Fig. 100.2). The rationale is that the device on the deaf side may allow the child to have improvement when hearing in noise. Overall, patients appear more satisfied with the device than with contralateral routing of signal hearing aids (107,108).

A traditional bone-conduction hearing aid may be used but has its disadvantages. The sound has to pass through soft tissue, and some sound energy is lost. When sound reaches the skull, they are transmitted with lower attenuation. This limitation is addressed with devices that directly couple the transducer to the skull such as with osseointegrated implants anchored into the temporal bone. The device depends on a percutaneous abutment in the postauricular area. A sound processor attaches to the abutment. A microphone within the sound processor receives sound, and vibrations are transmitted to the cochlea directly, bypassing the external and middle ear.

Figure 100.2 A 7-year-old girl with unilateral right profound hearing loss has a well concealed bone anchored hearing appliance.

The surgery usually is single stage in adults. A period of 3 to 4 months is necessary for osseointegration before the external processor is attached. In pediatric patients, the surgery is two staged because of the thinner skull, softer bone, and greater concerns about osseointegration (109). The fixture is placed subcutaneously with the initial step. After 3 to 6 months, the second stage surgery consists of thinning the skin flap and attaching the transcutaneous abutment to the fixture. For surgery in children with microtia and aural atresia, the position of the device is more posterior than the standard location. This permits for future ear reconstruction without potential compromise of the blood supply to the soft tissue.

Current FDA guidelines is for children 5 years and older, but the device has been placed in children less than 2 years of age. A nonsurgical strap may be used to secure the speech processor against the skin until the surgeon and patient is ready to proceed with surgery (110).

Complications associated with bone anchored prosthesis are not uncommon. The most frequent is problems with the surrounding soft tissue. In a large series of 149 patients, soft tissue reactions occurred in 3.4% of patients with three requiring removal of the device from the skin reaction (111). Others have reported the soft tissues complications around 7% (112) with pediatric series having higher complication ranging from 5.8% to 15.6% (113–115), but a recent publication of pediatric implants with longer term follow-up described the complication rate as high as 46.1% with 41.9% returning to the operating room for soft tissue revision (116). This risk was increased in those with a craniofacial syndrome.

Other main limitations of bone anchored appliances are the cosmesis and the need for daily management of the abutment that may be more accentuated in children. Recent advances in technology have resulted in newer options. The hearing appliance may be secured with an implanted magnet and thus adhere transcutaneously avoiding the need of a percutaneous abutment (117). Another novel mechanism is bone conduction through an orally worn device (118).

CONCLUSIONS

The newborn hearing screen has been important for the early diagnosis and habilitation of pediatric hearing loss. The shift to an earlier age of presentation has resulted in increase in initial physiologic assessment of hearing. The audiologist and otolaryngologist work in close collaboration for the diagnosis and management of pediatric hearing loss to assess auditory sensitivity and identify treatment options. These interventions have resulted in improving the speech and language outcomes of children with the hearing impairment.

HIGHLIGHTS

- 2 to 4 of every 1,000 infants born have hearing loss.
- Newborn hearing screen is possible with physiologic ABR and OAE.
- The goal of newborn testing is to screen by 1 month of age, diagnose hearing loss by 3 months of age, and initiate intervention by 6 months of age.
- Screening based on risk factors only detects 50% of infants with substantial congenital hearing loss.
- VRA permits behavioral threshold testing of infants at age 5 to 6 months.
- ABR testing provides essential information necessary for hearing aid fitting.
- The use of amplification by children is an ongoing process and necessitates frequent monitoring by the audiologist and otolaryngologist.
- Bilateral cochlear implants have their benefits with hearing in noisy environments and sound localization.
- Bone anchored hearing appliances provide an alternative to children who are not able to wear conventional hearing aids because of anatomical limitations or are poor surgical repair candidates.

Nongenetic Hearing Loss 101

Margaret A. Kenna

INTRODUCTION

Hearing loss is the most common congenital sensory impairment. Bilateral severe to profound hearing loss is present in 1 to 2/1,000 live births, and if unilateral and mild to moderate hearing losses are included, the number rises to 4/1,000. According to a recent National Health and Nutrition Examination Survey (NHANES) study, by the age of 12 to 19 years, the rate is 19.5% for any degree of hearing loss (1). The purpose of pediatric hearing evaluation is to identify the degree and type of hearing loss and its etiology and outline a comprehensive strategy that supports language, communication, and social development. Significant strides have been made in the early identification of hearing loss, as well as in diagnostic studies and long-term management. This chapter reviews newborn hearing screening and many of the nongenetic causes of hearing loss in infants and children.

History of Newborn Hearing Screening

The evolution and institution of newborn hearing screening occurred for several reasons: (a) availability of technology that provides rapid and accurate identification of hearing loss in newborns; (b) recognition that hearing can be tested easily and accurately in newborns; (c) recognition that early intervention in an infant with hearing loss supports significantly improved language outcomes compared to those identified later; and (d) the development of technologically improved assistive listening devices, including hearing aids, FM systems, and cochlear implants, which provide markedly improved hearing and awareness of useful sound in almost any infant or child with hearing loss.

Hearing screening has been performed in school-aged children in the public schools since 1927 and was able to identify hearing loss that could be educationally handicapping (2). Subsequently, in recognition that early identification of hearing impairment might lead to improved language, attempts were made to screen younger children aged 2 to 5 years. In 1979, Victor Goodhill, in his book *Ear Diseases, Deafness and Dizziness*, notes that "Parents are often *incorrectly* told that a child of this age cannot have accurate hearing testing" (3). However, appropriate services to support language development would not be provided until there was concrete evidence of the hearing loss.

In 1970, the Joint Committee on Infant Hearing (JCIH) recommended infant hearing screening as a research need and also recommended the widespread use of a high-risk register, which included one or more of the following: (a) history of hereditary childhood hearing impairment; (b) rubella or other nonbacterial intrauterine fetal infection (e.g., cytomegalovirus [CMV], herpes); (c) defects of the ear, nose, or throat; (d) malformed, low-set, or absent pinnae; cleft lip; or palate; (e) any residual abnormality of the otorhinolaryngologic system; (f) birth weight less than 1,500 g; and (g) bilirubin greater than 20 mg/100 mL serum. They further recommended that infants falling into any of these categories should be referred for an in-depth audiologic evaluation during the first 2 months of life, with regular follow-up evaluations even if the initial testing was normal. However, since only about 10% of newborns fall into the "high-risk" category and 50% of infants with communicatively significant hearing loss do not have any obvious high-risk features, it is apparent that the use of the high-risk register alone as a basis for hearing screening would miss up to half of the affected infants (4).

One of the significant early problems with newborn hearing screening was the lack of a reliable, rapid and easy to perform, and economical audiometric test. In 1896, Dr. Thomas Barr, in his Manual of Diseases of the Ear, noted that "we may employ the sound of a bell, a sharp whistle, or a very loud tone of voice, taking care that the

child does not see the source of the sound" (5). This essentially reflected the state of the art until the 1940s, when, in recognition of the difficulty in eliciting reliable behavioral responses in young infants, nonbehavioral audiometric techniques were developed. These included, in the 1940s and 1950s, electrodermal response audiometry, which used a conditioning paradigm that paired an auditory stimulus with a mild electric shock, with measurement of the galvanic skin response as an outcome. Additional tests based on conditionable autonomic responses included heart rate response audiometry (1950s to 1960s) and respiration audiometry (1960s to 1970s).

Subsequently, the Crib-O-Gram was developed by Blair Simmons at Stanford University (1974). It involved a motion-sensitive transducer that was placed on or under the infant's crib. A strip chart recorded any infant motor activity stronger than an eye blink or facial grimace before, during, and after presentation of auditory stimuli. The test was automated, noninvasive, and fairly easily performed. Using the Crib-O-Gram, the Stanford research group tested over 12,000 infants from 1974 to 1984. They found an incidence of hearing loss of 1:1,000 in the well-baby nursery and 1:52 in the neonatal intensive care unit (NICU), similar to current numbers for bilateral severe to profound hearing loss obtained using newer physiologic techniques. However, a number of variables affected the results, including a need to test when ambient noise was low and when the newborn's behavioral state was "right." Other issues included uncertainty about the optimal auditory stimulus, high false-positive and false-negative rates for babies with less than severe to profound losses, lack of ear-specific information, and poor test–retest reliability (6). The Auditory Response Cradle, developed in England in 1980 and similar to the Crib-O-Gram, was designed to evaluate several specific infant motor responses following programmed auditory stimuli. However, it was never widely used in the United States (7,8).

By 1986, six states had active statewide infant hearing screening programs, and in 1990, Blake and Hall reported that although 14 states had legislative mandates for newborn hearing screening, most of the other states still had no statewide policy. In addition, many states with legislative mandates did not have full implementation due to lack of funding, diversity of geography and population, lack of consensus about the most effective screening methods, and lack of follow-up programs (9). In 1990, the United States Public Health Service established the Healthy People 2000 project (10). Recommendations included a goal to "reduce the average age at which children with significant hearing impairment are identified to no more than 12 months." In 1993, the National Institute on Deafness and Other Communication Disorders sponsored a consensus conference on the *Identification of Hearing Impairment in Infants and Young Children* (11). The panel recognized that 50% of newborns with significant hearing loss did not have any high-risk factors and only about 10% of all newborns fell into any of the high-risk categories. Because use of the high-risk register alone would continue to miss many infants with congenital hearing loss, the panel recommended that universal newborn hearing screening be implemented during the first 3 months of life. A two-stage protocol of evoked otoacoustic emission (EOAE) screening followed by auditory brainstem response (ABR) screening for infants who failed the EOAE screen was recommended. In their 1994 position statement, the JCIH recommended that all newborns with hearing loss be identified by 3 months and that intervention be started by 6 months. The statement did not recommend ABR over otoacoustic emission (OAE) but recognized the advantages and limitations of each technique (12).

Three early universal hearing screening programs gave further weight to the need for universal newborn hearing screening. The first, in Florida in 1983 at Winter Park Memorial Hospital, screened 15,000 infants between 1983 and 1993 using automated ABR. Improved prenatal parent education and increased physician awareness that screening was possible were cited as two major positive outcomes. The second, in Colorado, occurred over three decades and by 1997 involved 22 hospitals. An incidence of 4:1,000 of bilateral or unilateral hearing loss was found, with no high-risk factors noted in 57% of the hearing loss group. The third study evaluated the Rhode Island Hearing Assessment Program. Based on extensive research on the detection of newborn hearing loss performed in Rhode Island in late 1980s and early 1990s, Rhode Island Public Law 23-23-13 became effective on July 1, 1993, mandating universal hearing screening of infants born in all 8 RI hospitals. Detection of transient evoked otoacoustic emissions (TEOAE) was chosen as the screening method, and all infants who failed a first TEOAE screen were rescreened using TEOAE. From January 1, 1993, to December 31, 1996, 52,659 babies were screened. Of the 10% referred for a second stage screen, 111 were found to have a permanent hearing loss, 45% NICU graduates and 55% well-baby nursery graduates. The NICU hearing loss rate was 9.75% and the well-baby nursery rate was 1.27%, for a combined rate of 2.12% (8).

In 1998, Christine Yoshinaga-Itano and her group in Colorado published the results of a study looking at language acquisition in children with hearing loss that was identified early (before 6 months) versus late (after 6 months). For all hearing impaired groups, there was significantly better language development in the early identification group (13). Finally, in 1999, the American Academy of Pediatrics published "Newborn and Infant Hearing Loss: Detection and Intervention" (14). This report recommended universal newborn hearing screening by 3 months of age with intervention by 6 months of age. The recommendations for screening were based on the fact that the five criteria for universal newborn hearing screening had been met: (a) easy to use test(s) with a high degree of sensitivity and specificity; (b) there was no other way to

detect the condition clinically (and in a timely fashion); (c) effective interventions were available; (d) early identification and intervention were associated with an improved outcome; and (e) the screening procedure was within an acceptable cost-effective range.

The current national goals for hearing screening were developed by the federal Early Hearing Detection and Intervention program. The first three goals, often called the 1-3-6 plan, are (a) all newborns will be screened for hearing loss by the age of 1 month, preferably prior to discharge from the hospital; (b) all newborns who screen positive will have a diagnostic audiologic evaluation before the age of 3 months; and (c) all infants with an identified hearing loss will receive appropriate early intervention services by the age of 6 months (15). The 2007 JCIH guidelines have been adopted by their member organizations, including the Alexander Graham Bell Association for the Deaf and Hard of Hearing, the American Academy of Audiology, the American Academy of Otolaryngology-Head and Neck Surgery, the American Academy of Pediatrics, the American Speech–Language–Hearing Association, the Council on Education of the Deaf, and the Directors of Speech and Hearing Programs in State Health and Welfare Agencies (16). In addition, hearing screening by age 1 month has been incorporated as one of the Healthy People 2020 Objectives (17,18). Currently all states and the District of Columbia screen over 95% of their newborns (19). However, neither the newborn hearing screening laws nor the implementation are uniform. Payment for hearing aids and early intervention services vary greatly, and follow-up continues to be a significant challenge in most states. Some of the reasons for loss to follow-up include underfunded newborn screening programs, challenging geography (rural areas with difficult access to follow-up facilities), cultural diversity, home births, between hospital transfers, and out of state births.

What Are the Downsides of Newborn Hearing Screening?

Newborn hearing screening is not without areas of concern. The physiologic tests used, ABR and OAE, are not 100% sensitive and specific; both false positives and false negatives do occur. The tests may need to be repeated several times, first in a screening mode and then in a diagnostic mode to give a definitive diagnosis. An infant may pass a screen only to be found after discharge to have a hearing loss, this may represent a false-negative test, the infant may have hearing loss that is too mild or in a frequency range that it is not detected by the screen, the hearing loss develops after discharge, or the screen used OAEs and the infant has auditory dyssynchrony. Errors in pass/fail parameters (i.e., how the machine is set) may "pass" patients when they should actually "fail" or "refer." It is also statistically possible that an infant can "pass" if the screen is repeated often enough, as most screens are designed with a balance in their sensitivity and specificity; for this reason, most newborn screening programs only allow one repeat screen, and if the infant still fails, then a diagnostic auditory evaluation is recommended. A "pass" may actually delay a hearing loss diagnosis. If the baby "passed" in error, or if a hearing loss occurred after birth but the baby passed the initial screen, the parents (and the primary care physician) will have a false sense of security, even if they feel the baby does not hear normally. A third possibility, recognized since screening programs became widespread, is that in protocols that use OAEs to screen rather than ABR, patients with auditory dyssynchrony spectrum disorder will often be missed.

Tests Used for Newborn Hearing Screening

Since auditory dyssynchrony spectrum disorders comprise up to 10% of hearing loss in infants, the use of both ABR and OAE as part of a hearing screening program in many ways would be ideal. In many cases, ABR or OAEs alone are able to detect even mild conductive or sensorineural hearing impairments. However, the use of both modalities is needed to make a definitive diagnosis of auditory dyssynchrony, especially in a neonate. In an infant with auditory dyssynchrony, robust OAEs may be present, yet on ABR tracings only a cochlear microphonic, followed by indistinct or absent ABR waveforms, will be seen. In screening programs using only OAEs, the diagnosis of auditory dyssynchrony may therefore be missed. It is important, therefore, that no matter which test is used for screening, follow-up diagnostic testing should utilize both modalities (20) (see Chapter xxx for further discussion of ABR and OAE testing).

The Role of the Otolaryngologist

The otolaryngologist is often one of the first physicians that the family and infant or child will meet in the course of the diagnosis of hearing loss. They may meet them at the time of their initial diagnostic ABR, for medical clearance for a hearing aid, or for further investigation into the etiology of the hearing loss. To be effective, the otolaryngologist must have some basic understanding of the support services needed and how to access them, and they should also be able to provide the family with some basic information about the possible causes of hearing loss. The otolaryngologist should be prepared to have at least a working knowledge of OAEs and ABR. and behavioral audiometry, as well as interventions including hearing aids, FM systems, and cochlear implants.

CAUSES OF HEARING LOSS IN INFANTS AND CHILDREN

Defining the cause of the hearing loss can provide prognostic as well as educational information to the family. Careful evaluation can now pinpoint a definite or probable cause of the hearing loss 50% to 60% of the time. The etiologies

of hearing loss have often been divided into congenital and acquired. However, many of the causes that are congenital were "acquired" *in utero* and may only present at a later time (e.g., delayed onset of sensorineural hearing loss [SNHL] from CMV); this is in contrast to those truly acquired after birth (e.g., secondary to extracorporeal membrane oxygenation [ECMO], meningitis, or trauma). Although it is important to know if the hearing loss is pre- or postlingual in onset for management purposes, a more useful way to look at hearing loss etiology is to divide the etiologies into infectious, anatomic, genetic, traumatic, ototoxic (and other issues related to NICU stays), and other. The degree and laterality of the hearing loss in many of the causes of hearing loss are similar, with potential overlap between some of these causes, making the identification of a definite etiology more challenging. Some examples of this include children with enlarged vestibular aqueducts (EVAs) and mutations in the SLC26A4 gene (a genetic cause with an anatomic presentation); NICU stays involving possible combinations of ototoxicity, ECMO, prolonged ventilation, and hyperbilirubinemia; and more than one statistically common cause presenting in the same child, for example, congenital CMV and mutations in the *GJB2* (Connexin 26) gene. Similarly, "genetic" may be a more accurate way to describe "hereditary" hearing loss, as many families think hearing loss can be genetic only if it presents in a dominant pattern, while most genetic congenital and early onset hearing loss is recessive (so the parents do not usually manifest the hearing loss). Other common inheritance patterns that may result in hearing loss include X-linked recessive (the mothers/sisters who are carriers do not usually have the hearing loss), X-linked dominant (mother would be symptomatic), mitochondrial (which is highly variable so the mother may be asymptomatic), or multifactorial (gene and environment interaction). Similarly, some genetic causes of hearing loss may be due to *denovo* mutations (arising in germ cells or in the embryo itself) so that neither parent would be expected to have that same mutation. See Chapter xxxx for an in-depth discussion of genetic causes of hearing loss.

Infectious Causes

Infectious causes of hearing loss can occur both before and after birth. Historically, the TORCHES (**T**oxoplasmosis, **O**ther, **R**ubella, **C**ytomegalovirus, **H**erpes virus, **S**yphilis) organisms are described as common causes of congenital hearing loss due to prenatal exposure. However, as the epidemiology of these organisms has changed, only one, CMV, is currently a substantial cause of congenital hearing loss in many countries.

Toxoplasmosis

Toxoplasmosis is caused by the protozoan parasite *Toxoplasma gondii* and, if acquired prenatally, can cause SNHL. Toxoplasmosis is acquired by exposure to undercooked meat, cat feces, soil, or water containing the parasite. The overall prevalence and incidence of congenital toxoplasmosis varies by region and country. In much of the United States, toxoplasmosis is not considered a reportable disease, making it difficult to get accurate incidence figures. Reporting is seriously hampered by the fact that primary infection in most adults (and therefore pregnant mothers) is asymptomatic. In 2000, the Centers for Disease Control and Prevention (CDC) reported that there were an estimated 400 to 4,000 cases of congenital toxoplasmosis in the United States, based on the seroconversion rate of pregnant mothers (21). Massachusetts began screening newborns for toxoplasmosis in 1986, and in 1994 a study from the New England Regional Newborn Screening Program found the incidence of toxoplasmosis in newborns to be 1/10,000 (22). From 1986 to 1998, a total of 99 cases was detected through this program in Massachusetts, but at least 6 cases eventually diagnosed cases were missed by the screening. The incidence of congenital toxoplasmosis varies outside the United States, estimated at 6 per 1,000 births in France, 2 per 1,000 births in Poland, 7 to 10 per 1,000 births in Colombia, and 3 per 1,000 births in Slovenia (23).The NHANES from 1999 to 2000 reported that of the 2,221 women aged 18 to 49 years tested for IgG antibodies to *Toxoplasma* 14.9% were positive, meaning that the remainder of the women were susceptible to primary infection. Mothers who become primarily infected with *T. gondii* have approximately a 30% to 50% chance of transmitting the infection to their fetus. Although the most severe disease is experienced by fetuses becoming infected during the first trimester, transmission of infection, which is transplacental, is much more common later in pregnancy, especially during the third trimester, or during delivery. Eighty-five percent of infants with congenital toxoplasmosis are asymptomatic at birth, with those infected later in pregnancy most likely to be asymptomatic. Although vertical transmission of infection is most likely to occur with primary maternal infection, immunocompromised women with chronic infection may also pass on the disease. If new infection is detected in the mother early in pregnancy, treatment with oral spiramycin, which does not cross the placenta, can prevent transmission to the fetus. If infection occurs later in pregnancy, and/or if the fetus is also infected, treatment with pyrimethamine, sulfadiazine, and folinic acid (pyrimethamine is a folic acid antagonist) may prevent transmission to the infant by treating the mother and may also treat the fetus (24).

The classic symptoms of congenital toxoplasmosis are chorioretinitis, hydrocephalus, and intracranial calcifications. Other symptoms, which can also be seen in other congenital infections including CMV, herpes, and rubella, may include hepatosplenomegaly, jaundice, anemia, microcephaly, and lymphadenopathy. Although a recent systematic review by Brown et al. (25) did not find any cases of hearing loss in infants with congenital toxoplasmosis, others have reported an incidence from 0% to 20%. Earlier studies with a higher incidence of SNHL

often included untreated infants, while most infants in recent studies had been treated, suggesting that adequate treatment decreases the occurrence of SNHL. Treatment of congenitally infected infants with pyrimethamine and sulfadiazine is generally effective, although infants who present without neurologic disease have somewhat better outcomes than those who present with neurologic impairment. In addition, babies asymptomatic at birth may develop signs later in life, including chorioretinitis (25).

Rubella

Rubella is caused by a togavirus of the genus Rubivirus. Until the introduction of the rubella vaccine, rubella was the most common viral cause of congenital SNHL. The rate of congenital rubella syndrome (CRS) for infants born to women infected during their first 11 weeks of pregnancy is 90%; if infected during the first 20 weeks of pregnancy, it is 20%. The most common features of CRS are cataracts, heart defects, and hearing impairment. During the 1962 to 1965 global rubella pandemic, there were an estimated 12.5 million rubella cases in the United States, and 20,000 infants developed CRS. Following the licensure of live attenuated rubella vaccines in the United States in 1969, the number of reported cases of CRS declined 99%, from 77 cases in 1970 to one imported case in 2004. Although rubella is no longer endemic in the United States, it continues to be endemic in many other countries, where vaccination rates may also not be uniformly high in postpubertal females. Therefore, babies with congenital hearing loss born outside the United States in areas where rubella remains endemic, or born to mothers who may not have been vaccinated, may be more likely to have CRS as a cause of their hearing loss. According to the World Health Organization, the number of countries that have incorporated rubella vaccine into their immunization programs increased from 83 countries (13% of the birth cohort) in 1996 to 127 countries in 2008. In addition, the development of CRS is a theoretical risk in infants of mothers vaccinated during pregnancy, although this has not been reported in the literature. Any infant with CRS can shed the virus for up to 1 year after birth, so that all unvaccinated female caretakers should be aware that they may be at increased risk to become infected (26,27) (http://www.who.int/immunization/newsroom/Global_Immunization_Data.pdf).

Cytomegalovirus

Prenatal exposure to CMV, a beta-herpes virus, is the most common congenital viral infection and currently the most common viral cause of congenital SNHL. A 2008 study in Dallas, Texas, by Stehel et al. documented a 6% incidence of congenital CMV in babies with confirmed hearing loss. The prevalence of congenital CMV infection is approximately 0.4% to 2.3% of all newborns. If the mother has a primary CMV infection during pregnancy, there is a 40% chance that the infant will become infected, and if she has a reactivation infection, there is about a 2% chance. The chance of transmission of primary infection from mother to child is 25% in the first trimester, 50% in the second, and 75% in the third. However, infants exposed to the virus during the first trimester are the most likely to develop serious neurologic sequelae. Although 90% of infants with congenital CMV are asymptomatic at birth, 10% to 15% will develop hearing loss, while 65% to 70% of infants with symptomatic CMV infection will develop hearing loss. In the study by Stehel et al. (28), 75% of the infants with congenital CMV were only diagnosed because they had hearing loss. However, since CMV hearing loss may be present at birth or it may not develop until later in infancy/childhood, the diagnosis can easily be missed (29). Infants with symptomatic CMV may present at birth with microcephaly, intrauterine growth restriction, developmental delay, hepatosplenomegaly, chorioretinitis, jaundice, petechiae, thrombocytopenia, hyperbilirubinemia, anemia, and hearing loss. The diagnosis of congenital CMV is made in the first few weeks of life by shell vial culture using saliva or urine. Recently, investigators have evaluated CMV polymerase chain reaction (PCR) using dried blood spots, liquid and dried saliva, and dried umbilical cord (30). Although PCR from any of these sources has not been found to be as sensitive as shell vial culture in the newborn period, positive PCR using dried blood spots can confirm a diagnosis of congenital CMV outside the newborn period when shell vial or CMV IgG cannot differentiate between congenital and postnatally acquired infection (31). In addition, PCR technology may be a basis for large-scale screening. Currently, treatment for the hearing loss involves at least 6 weeks of ganciclovir, or, more recently, valganciclovir, a pro drug of ganciclovir (32,33). The optimal duration of therapy remains unclear, with some evidence supporting a longer course of therapy (up to 6 to 12 months). Although several studies support improved hearing with either of these drug regimens, the numbers of treated patients remain small, the follow-up is variable, and progression of the hearing loss may occur after the drugs are stopped. Side effects of ganciclovir and valganciclovir include bone marrow suppression (neutropenia, thrombocytopenia, anemia) and kidney and liver toxicity. Teratogenesis, mutagenesis, inhibition of spermatogenesis, and impaired fertility have been reported, primarily in animal studies, as a result of exposure to these agents. In addition, treatment of older children with progressive hearing loss due to congenital CMV has not been studied.

Once the baby is out of the newborn period, making a definite diagnosis of congenital CMV is difficult. It can be suspected, however, based on findings of developmental delay, microcephaly, and hearing loss. Visual impairment may be present in 10% to 20% of symptomatic babies and includes strabismus, optic atrophy, macular scarring, pigmentary retinitis, and visual loss. Boppana et al. (34) has reported late onset or reactivation chorioretinitis in 7/31 (23%) of children after 1 to 10 years of age. Imaging findings can help narrow the diagnosis in older children, or

confirm the diagnosis in newborns. Intracranial calcifications, migrational abnormalities (e.g., polymicrogyria), cerebral and cerebellar volume loss, ventriculomegaly, and white matter disease are commonly seen on a combination of ultrasound, magnetic resonance imaging (MRI), and computed tomography (CT). Characteristic imaging findings in association with neurodevelopmental delay strongly suggests a diagnosis of congenital CMV.

The prevention of congenital CMV is a major public health issue. CMV infection in healthy adults and children is common, often silent, and chronic, with viral shedding in urine and saliva continuing for months or years. This makes avoidance of infected individuals by pregnant women, although desirable, almost impossible. The timing of pregnancy related to when the mother developed a primary CMV infection has been found to affect whether subsequent infants develop CMV. Fowler et al. (35) found that for mothers who were initially CMV nonimmune or immune, a shorter interval between the birth at which the mother's serologic status was established and the subsequent birth was associated with an increased risk of congenital CMV. It was also clear from this study that maternal CMV infection that occurs before getting pregnant still results in a substantial risk of congenital CMV.

However, because preconception maternal CMV immunity may confer a significant degree of protection against vertical transmission of the virus compared to primary infection during pregnancy, vaccination of young women before they get pregnant is an obvious route to protection (35). Although the development of an effective CMV vaccine has been difficult, Schleiss (36) has recently reported interim results of a phase II trial of a deoxyribonucleic acid (DNA) vaccine against CMV in a guinea pig model. Further population-based studies of transmission rates, severity of disease related to when the mother and fetus become infected, and vaccine development will be key to decreasing the overall prevalence and transmission of CMV in the population.

Herpes Simplex

Herpes simplex virus types 1 and 2 (HSV-1 and HSV-2) are double-stranded DNA viruses that commonly infect humans (37). Neonatal HSV infections occur in approximately 1/3,200 births in the United States, with the majority being HSV-2 (37). Kimberlin (38) reported that 85% of transmission is peripartum, 10% is postnatal, and 5% is *in utero*, with primary maternal infection resulting in a higher transmission rate than reactivation disease. Approximately 50% of neonatal HSV infections have central nervous system (CNS) involvement. The incidence of hearing loss in children with neonatal HSV is unclear. A recent systematic review of the incidence of SNHL in neonates exposed to HSV was published in 2008 (39). They found that SNHL occurs rarely in infants with exposure to HSV and that there was no evidence of delayed onset of SNHL in infants with asymptomatic perinatal HSV infection. The few papers that reported audiometric data found hearing loss in association with intrauterine HSV-2 infection 0% to 33% of the time, with all infants also having severe CNS disease. However, all studies were small and audiometric techniques varied. The standard treatment for symptomatic perinatal HSV infection is acyclovir, but the effect of treatment on hearing loss is unclear. Based on the limited information available, Westerberg et al. (39) did not find that routine serologic screening for HSV infection in otherwise asymptomatic neonates with SNHL was justified.

Syphilis

Transplacental mother-to-child transmission of syphilis has been recognized since the 15th century. Congenital syphilis (CS) and syphilis acquired after birth are caused by *Treponema pallidum*, a gram-negative spirochete bacterium. Worldwide, 2 million mothers test positive for syphilis during pregnancy, comprising 1.5% of all pregnancies, and can lead to stillbirths and neonatal death. In the United States, however, CS is uncommon, with the result that hearing loss due to CS may be missed. A systematic review of CS cases and articles contained in multiple databases, including Medline (1950 to March 2008), EMBASE (1980 to March 2008), CINAHL (1982 to March 2008), BIOSIS Previews (1969 to March 2008), and Cochrane databases, was published in 2009 (40). These authors found no reported cases of SNHL in infants with CS born to mothers with syphilis acquired during pregnancy in any of the articles they reviewed. Between 2003 and 2005, the number of CS cases reported annually in the United States declined from 10.6 cases per 100,000 live births in 2003 to 8.2 in 2005, but then increased back to 10.1 per 100,000 live births in 2008. This increase in CS followed a 38% increase in the primary and secondary syphilis rate among US females from 2004 to 2007. In 2008, infants born to black mothers accounted for 50% of CS cases, infants of Hispanic mothers for 31% of cases, and infants of white, Asian/Pacific Islander, and American Indian/Alaskan Native mothers for 15%, 2%, and 1%, respectively. Despite this recent increase, however, CS remains uncommon in the United States, and therefore CS and any associated hearing loss may not be as readily recognized as in countries where it is more common. Hutchinson described the classic triad of late CS as interstitial keratitis, notched incisors, and SNHL (41). In 1970, Fiumara and Lessell (42) added to this triad Clutton joint (symmetrical hydrarthrosis especially of the knees) and mulberry molars (malformed first molar resembling a mulberry). Although any infant who presents with nonimmune hydrops, osteochondritis, periosteitis, hepatosplenomegaly, jaundice, rhinitis, mucocutaneous skin rash, and/or pseudoparalysis of an extremity should be suspected of having CS, there are no studies looking at the array of symptoms in infants who are actually serologically positive, raising the question whether hearing loss could be the only symptom of CS. Prenatal diagnosis involves testing pregnant mothers, with nearly complete elimination

of any serious complications in the baby if the mother is treated before 24 weeks gestation. For babies with CS identified after birth, appropriate treatment with penicillin (dose and duration dependent on formulation) usually results in a cure. If there is uncertainty about whether the mother has been adequately treated, evaluation of both the mother and infant should be undertaken shortly after birth. Syphilis acquired after birth may present as progressive and/or sudden hearing loss or vertigo. Therefore, the diagnosis of acquired syphilis should be considered in any sexually active patient who presents with recent onset hearing loss and/or vertigo, as these symptoms often improve with penicillin and steroids.

Other Infectious Diseases Associated with Hearing Loss

HIV

Audiologic and vestibular symptoms can occur in children infected with human immunodeficiency virus type 1. These include conductive hearing loss (often due to otitis media), SNHL, tinnitus, vertigo, and ataxia. Hearing loss may occur due to direct infection of the inner ear with human immunodeficiency virus (HIV), or secondary to opportunistic infections (e.g., CMV, syphilis, tuberculosis, cryptococcal meningitis) or ototoxic drug therapy. In a 2008 study, 23 Mexican children with HIV on highly active antiretroviral therapy aged 5 months to 16 years underwent pure tone audiometry, speech discrimination testing, ABR testing, electronystagmography, and rotary chair testing. Most children had acquired their HIV perinatally. Although not every child was able to be tested using all techniques, six children had conductive hearing loss (related to a history of otitis media), one had SNHL, one had a mixed hearing loss, others had abnormalities on ABR reflecting dysfunction at varying levels, and several had vestibular hyporeflexia. Although not statistically significant, there was a suggestion that lower CD4 counts, longer time with HIV, and higher viral load were associated with an increased prevalence of audiologic or vestibular symptoms (43).

Measles (Rubeola)

Measles is a paramyxovirus spread via the respiratory route and, in the prevaccine era, was an identified cause of acquired hearing loss, although the incidence was not well defined. Although measles was reported to have been eradicated in the United States in 2000, hundreds of cases have been reported since then, occurring mainly in children born outside the United States, children too young to vaccinate, and in those children whose parents have intentionally not vaccinated them. Live attenuated measles virus is included in the standard measles vaccine. A paper using information from the Vaccine Adverse Event Reporting System in the United States from 1990 to 2003 estimated the reporting rate of SNHL possibly related to mumps/measles vaccine to be one case in 6 to 8 million doses (44). Measles virus has also been possibly implicated in the development of otosclerosis, although whether this is an association or causation remains unclear (45,46).

Lyme Disease

Lyme disease is caused by the bacterium *Borrelia burgdorferi* and is transmitted to humans by the bite of an infected black-legged tick. The incidence is highest in the United States in east coast states and Wisconsin and Minnesota but has been reported in all 50 states. Although people of any age and both genders are susceptible to tick bites, Lyme disease is most common among boys aged 5 to 19 and persons aged 30 or older. The CDC reported an 8% incidence of facial palsy among 119,965 patients with Lyme disease between 1992 and 2004. Hearing loss in association with Lyme disease, however, is infrequently reported (47). A 2010 retrospective review by Wilson et al. of patients 18 years of age and older presenting with asymmetric SNHL of uncertain etiology showed that of the 88 who were tested for Lyme disease, 3 were positive. Although the endemic nature of Lyme disease in many parts of the country can make confirming a relationship between Lyme disease and hearing loss challenging, Wilson et al. (48) felt that of the many tests ordered in this study, Lyme titers and tests for syphilis were potentially the most useful and cost-effective.

Mumps

Mumps is a paramyxovirus that results in an acute viral illness characterized by unilateral or bilateral parotitis, and complications include SNHL, aseptic meningitis, encephalitis, and, in postpubertal age groups, orchitis, oophoritis, and mastitis. Approximately 20% to 40% is asymptomatic, and many symptomatic patients only have respiratory symptoms. Mumps is endemic in most of the world, and by July 2010 was included in the vaccine programs of 117/193 (61%) of the World Health Organization member states. Live mumps vaccine was licensed for use in the United States in 1967, with a drop in incidence of mumps cases to 0.1 cases/100,000 persons (314 cases total) in the United States by 2005. However, there have been two large outbreaks of mumps since then, in 2006 and 2009. The incidence of SNHL after mumps is unclear, but a 2009 study from Japan suggested an incidence of 0.1%, with the hearing loss being unilateral and in the moderate to profound range (49). Hearing loss associated with mumps may occur before or after the parotitis and in otherwise asymptomatic cases. The vaccines against rubella, measles, and mumps contain live attenuated virus, and hearing loss in association with measles, mumps, and rubella vaccine has also been, although rarely, reported (50). A 2007 paper from the CDC estimated the reporting rate of SNHL related to vaccine use to be one case in 6 to 8 million doses. Because of the rarity of these reports, a causal relationship between mumps, rubella, and measles vaccination and SNHL requires further study (51,52).

Bacterial Meningitis

Hearing loss is a well-documented sequela of bacterial meningitis. A 2010 systematic review and metaanalysis of 132 papers from around the world published between 1980 and 2008 reported a 33.6% incidence of hearing loss due to bacterial meningitis from all causes (*Streptococcus pneumoniae, Haemophilus influenza type B (HIB), Neisseria meningitidis*, other) (53). Although HIB meningitis was the most common, hearing loss occurred most often after pneumococcal meningitis. Worsoe et al. (54) studied a Danish cohort of patients who had pneumococcal meningitis between January 1999 and December 2003. Of the 502 original patients, they located 343 (many had died or emigrated), and of those, 240 had audiometric testing. They found an overall incidence of hearing loss in these 240 patients of 54%; 47% under the age of 2 years had hearing loss, and 79% of individuals over the age of 2 had hearing loss. Seven percent had unilateral profound SNHL and seven percent had bilateral profound SNHL. In addition, many patients who were not suspected of having hearing loss at the time of discharge after the meningitis were later found to have SNHL, supporting the need for close follow-up. The use of systemic steroids in the management of meningitis remains controversial (54). In 2010, Van de Beek et al. (55) published a metaanalysis of individual patient data from 2,029 subjects (41% children less than 15 years) who participated in one of five prospective randomized double blind placebo controlled trials of dexamethasone use in acute bacterial meningitis. In HIV-negative adults, dexamethasone was associated with a reduction in death or severe neurologic sequelae, including severe bilateral hearing loss. However, this effect of dexamethasone was not present in HIV-negative children, or in HIV-positive children and adults. A Cochrane database review, also from 2010, looked at 24 randomized controlled trials of corticosteroids (4,041 subjects) for acute bacterial meningitis. For the group as a whole, they found a significantly reduced rate of hearing loss and neurologic sequelae, although overall mortality was not reduced. Of interest, the data supported the use of corticosteroids in high-income, but not low-income, countries, as no beneficial effect of steroids was found in low-income countries (55). Finally, a study by Peltola et al. (56) of children aged 2 months to 16 years with bacterial meningitis found that age and clinical presentation, but not whether the patients got steroids or glycerol, had a measurable association with hearing outcome. The benefits of dexamethasone or other steroids in the prevention of hearing loss or other neurologic sequelae due to bacterial meningitis continue to remain unclear (56,57).

Bacterial meningitis–related hearing loss has its onset early in the course of the disease, and the incidence has not been decreased by any specific antibiotic regimen. Although otitis media with direct spread through labyrinthine windows may precede onset of the disease in some cases, a more likely route is penetration of bacteria and bacterial toxins via the cochlear aqueduct or internal auditory canal contents, resulting in perineuritis or neuritis of the cochleovestibular nerve and/or suppurative labyrinthitis. Other pathophysiologic mechanisms operative in producing hearing loss may include serous or toxic labyrinthitis, thrombophlebitis or embolization of labyrinthine vessels, and hypoxia or anoxia of the eighth nerve and central auditory pathways.

If a child with meningitis has normal audiometric studies after the first few days of antibiotic therapy, it is unlikely that significant SNHL will develop later, and some children with initially abnormal hearing may improve, suggesting a resolving serous labyrinthitis. A few individuals with documented mild to moderate hearing losses after discharge have shown some improvement over time, while more severe losses, in some children, have fluctuated for as long as a year after hospital discharge. Well-documented late progression of postmeningitic SNHL after years of stability has been reported in a few cases.

HEARING LOSS SECONDARY TO TRAUMA

There are many different categories of trauma that can result in hearing loss in children, including head trauma, exposure to ototoxic medications, chemotherapy and radiation therapy, ECMO, iatrogenic injury due to surgery, and noise. Of all of these, environmental noise is the most common.

Noise-Related Hearing Loss

Decades ago, investigators found that the human ear, when exposed to loud sounds long enough, will permanently lose some hearing. The outer hair cells in the cochlea, when exposed to loud noise, initially experience transient damage that causes a temporary threshold shift in the hearing; if the person is exposed long enough, the damage becomes permanent. Standard pure tone audiometric tests do not capture these early changes, so by the time you can "see" the hearing loss in the audiogram, permanent damage has been done. Governmental agencies, including the Occupational Safety and Health Administration and the National Institute for Occupational Safety and Health, have guidelines for occupational and industrial noise exposure and require that individual workers exposed to sound levels greater than 85 dB wear ear protection. These guidelines are based on a calculation of noise "dose," using formulas that include total time of exposure at a specific noise level. These guidelines show how, above 85dB, the potential for permanent hearing loss increases rapidly with seemingly modest increases in decibel level. Because decibels are measured on a logarithmic scale for every 3 dB increase in sound pressure, the amount of allowable exposure to noise above 85 dB is cut in half (58,59).

Technology has made music, news, videos, and other media instantly available. Personal cassette players were

introduced in the 1970s, CD players in the 1980s, and MP3 players in the late 1990s. Because of this, hearing loss due to noise exposure is no longer limited to construction workers, hunters, and rock musicians; now anyone can get it. Several studies since the 1980s have documented the potential dangers to hearing secondary to portable music players. These studies found that, in addition to listening to music devices for several hours a day, many people listen in the presence of background noise, thus turning up their music players above a safe level. Since the average background noise level of an occupied cafeteria is 85 dB and the interior of a moving car 40 to 80 dB (depending on road surface, etc.), it is easy to see why people might turn up their music players (60–64).

A 2004 report found that the output levels of common earphones, including insert, supra-aural, vertical, and circumaural, varied across type and manufacturer, but generally the sound pressure level in decibels was highest for the smallest earphones, and that insert earphones increased the output level 7 to 9 dB. In a few CD player–headphone combinations, output exceeded 130 dB. Currently, all common MP3 players can produce sound pressure levels of more than 100 dBA using the earbuds supplied with the players. A recent 2007 article recommends that people using a standard personal music player and headphone combination should limit their listening to no more than 60% volume for 60 minutes (or less) for a CD player and no more than 90 minutes (or less) at 80% volume for a MP3 player during any 24-hour period. Additional recommendations are to use sound-isolating earphones in the presence of significant background noise (and if difficulty hearing your background noise does not pose a safety issue). The use of these earphones has been shown to provide as much as 25 dB of sound isolation.

Finally, a 2010 JAMA article based on NHANES for 1988 to 1994 and 2005 to 2006 found that there has been an increase in the prevalence of hearing loss for those participants aged 12 to 19 years from 14.9% in 1988 to 1994 to 19.5% in 2005 to 2006 ($P = 0.02$) (1). In addition, the hearing loss was more prevalent in males (both time periods) and was more frequently unilateral and high frequency in 2005 to 2006. Because the NHANES is cross sectional, associations with particular risk factors cannot be ascertained. However, the increasing use of personal listening devices and exposure to other loud noise sources certainly suggests that these may be factors in the recent increase in hearing loss in young people; further work is needed to see if this increase change is statistically related to noise exposure. In addition, the exposure to noise in the setting of other risk factors for hearing loss, such as systemic aminoglycosides, chemotherapy, and genetic factors, needs to be studied.

Ototoxicity

Several groups of drugs are well-recognized causes of SNHL, including aminoglycoside antibiotics, systemic chemotherapy (especially cisplatin), macrolides, and loop diuretics. The effects of these drugs on inner ear physiology may be compounded by concurrent medical conditions, including renal failure, the use of ECMO, sepsis, extreme prematurity, diabetes, noise exposure, and genetic factors, all of which are independently related to an increased incidence of hearing loss. Hearing loss related to these drugs may occur both during and long after administration, especially for cisplatin. Radiation therapy involving the temporal bones and cisplatin given within the same time frame have been reported to have an increased incidence of SNHL over either one alone, with the hearing loss often presenting years after the therapy is completed. While the ototoxicity of the aminoglycosides is strongly related to drug levels (peaks and troughs) and cumulative dosage, mutations in mitochondrial genes, especially the homoplasmic 1555A>G and 1494C>T mutations in the mitochondrial 12S rRNA, provide increased susceptibility to aminoglycoside ototoxicity, with hearing loss occurring after even one dose in some cases in patients who have these mutations. Hearing loss after exposure to macrolides is often reversible when the drugs are discontinued (65–71).

Mutations in the 12S rRNA genes also are associated with nonsyndromic SNHL in the absence of aminoglycoside exposure. Although the incidence of these mutations varies widely between populations, screening of certain populations at risk for ototoxicity due to the medical management of their disease, such as adult patients with cystic fibrosis, may identity those who are at increased risk for aminoglycoside-related ototoxicity. This knowledge would potentially allow modification of their medical regimen, decreasing the possibility of hearing loss. In addition, there has been increasing interest in preventing or moderating ototoxicity in patients requiring ototoxic medications, including recent studies evaluating aspirin, amifostine, and melatonin and 17-β-estradiol. It is likely that these types of investigations will provide new insight into both prevention of hearing loss as well as mechanisms of the hearing loss itself.

Prevention of hearing loss due to noise and chemotherapy is desirable. Although avoidance of ototoxic exposures will always be the first step in the prevention of hearing loss, in situations where these exposures are not preventable, methods to ameliorate the ototoxic effects are important. For noise, the use of physical barriers, such as specialized head phones, turning down the volume, and decreased overall exposure, are effective. However, pharmacologic means to prevent hearing loss are also being investigated and include the experimental use of *N*-acetyl-cysteine, D-methionine, and salicylates.

Head Trauma

It is well known that temporal bone fractures are associated with SNHL. Much less well recognized is the incidence of hearing loss due to closed head trauma, such as concussion and traumatic brain injury, in the absence of

obvious temporal bone fractures. In a recent study of soldiers returning from Iraq and Afghanistan, over half of the subjects with traumatic brain injury had hearing impairment, and many had both visual impairment and hearing loss (72). These subjects exhibit both peripheral hearing loss as well as more subtle central auditory findings, potentially making rehabilitation more challenging. With an increasing recognition of the prevalence of cognitive and behavioral effects of sports-related concussion as well as traumatic brain injury, adding an auditory evaluation to the clinical care of these patients should be considered.

SUDDEN SNHL

Sudden SNHL is a well-reported occurrence in adults but little discussed in children, although several published series include children. Although the definition of idiopathic sudden SNHL includes unilateral onset, many subjects with sudden onset of SNHL have bilateral findings. The causes of sudden onset SNHL are often difficult to identify, but Hughes et al. (73) list viral, immunologic, traumatic, neoplastic, vascular, toxic, neurologic, and metabolic as potential etiologic factors. Other causes could include unwitnessed head trauma, barotraumas, sudden auditory manifestations of preexisting temporal bone abnormalities (e.g., EVA, eighth nerve tumors) Meniere's disease, progression of unrecognized congenital infections (such as CMV, toxoplasmosis, syphilis), Lyme disease, or an underappreciated manifestation of a previously existing disease, such as the hereditary periodic fever syndromes (73). Ioannis et al. (74) studied the records of 48 children with sudden hearing loss presenting to their department between 2002 and 2007. Twenty-six (54%) were found to have pseudohypacusis. Of these, 16 were girls and the mean age was 10.5 years, in good agreement with existing literature. Of the 22 cases (46%) with true organic hearing loss, 2 had EVA, one had multiple sclerosis, one had Herpes virus, 2 had acoustic trauma, and the remainder were considered idiopathic. Suggested treatments for sudden SNHL (without an obvious etiology) include systemic steroids, intratympanic steroids, and antivirals, although nearly all treatment series only include patients over 18 years of age (74). Systemic steroids have been studied the most, with generally modest to mild benefit reported if they are started soon after the SNHL is identified. Huang and Sataloff (75) reported on seven children with autoimmune inner ear disease, with both systemic steroids and cytotoxic medications having some efficacy. In terms of antivirals, a study by Tucci et al. (76) looked at hearing improvement in patients over 18 years of age with idiopathic SNHL treated with systemic prednisone with or without valacyclovir (antiviral) therapy. No additional benefit over steroids alone was noted in the valacyclovir patients in this trial, or in two other trials using antivirals (76). Intratympanic steroids, as first or salvage treatment, have also recently been studied. Most studies have small numbers, are retrospective, are limited to case series, do not include a natural history group, and do not include large numbers of (or any) children. The efficacy of intratympanic steroids therefore remains unclear. Other therapies mentioned in the literature, including hyperbaric oxygen, volume expanders, vasodilators, herbal remedies, anticoagulants, and zinc, have not been studied in a rigorous fashion in any age group for sudden SNHL (77).

Hearing Loss in Babies Who Require Newborn Intensive Care Unit Management

It is well recognized that NICU infants, especially those with very low birth weight (VLBW; below 1,500 g), have a higher incidence of hearing loss than term infants in the well-baby nursery. The incidence of SNHL in VLBW babies varies between studies, but overall the incidence seems to be decreasing. Three studies between 2000 and 2006 found an incidence of possible hearing loss of 12.8% to 31.6% using OAE screening, but only 2% subsequently had hearing loss based on diagnostic ABR testing. During a similar time period, multiple studies found an incidence of newborn hearing loss in several general populations of 0.11% to 0.9%. Risk factors associated with permanent congenital, delayed onset, or progressive hearing losses are listed in the JCIH 2007 guidelines. A NICU stay of more than 5 days or the presence of any of the following raise the level of concern: ECMO, assisted ventilation, ototoxic drug exposure, loop diuretics (furosemide), and hyperbilirubinemia requiring exchange transfusion. A 2009 study by Robertson et al. studied 1,279 survivors born at a birth weight of ≤1,250 g and a gestational age of ≤28 weeks between 1979 and 2003 in Alberta, Canada. Although there was a marked improvement in the degree surviving over time (26% survived in 1974 to 1976 compared to 88% in 2001 to 2003), the percentage with hearing loss at age 3 years did not change. The overall rate of hearing loss of any degree was 3.1%, with a 1.9% rate of severe to profound hearing loss. One child was found to have auditory dyssynchrony, 4 (10%) had delayed onset of bilateral hearing loss, and 11 children (28%) had progressive hearing loss. They found prolonged use of supplemental oxygen beyond 36 weeks to have the strongest association with all degrees of hearing loss. Several additional factors they included that were markers for hearing loss were the need for gastrointestinal surgery, (colonostomy, ileostomy, or resection associated with necrotizing enterocolitis), patent ductus arteriosus ligation, and lower socioeconomic status. Additional studies have shown a statistical association between hearing loss and severe hypoxic/ischemic encephalopathy, prolonged mechanical ventilation, persistent pulmonary hypertension, higher serum bilirubin, intraventricular hemorrhage and meningitis, and high-frequency ventilation. Whether some of these are related directly to the hearing loss or occur as a result of factors that may also lead to hearing loss remains unclear (78–81). In some studies, aminoglycoside

use, long suspected of being a major risk factor for NICU-related hearing loss, is found to be only slightly statistically associated. This could be due to better monitoring of peak and trough levels or better management of NICU babies with decreased need for prolonged aminoglycoside courses. The use of loop diuretics (furosemide and ethacrynic acid) is associated with hearing loss in newborns. Of particular concern is that they potentiate the rate of aminoglycoside-induced hearing loss and may also be more likely to cause hearing loss in the presence of sepsis. Finally, noise in the NICU, generated by the presence of life support equipment, has been shown to be a contributing factor to hearing loss in NICU infants. Li and Steyger (82) and Li et al. (83) have recently suggested a mechanism for the synergistic effects on hearing of aminoglycosides and noise in humans and note that subdamaging doses of aminoglycosides may make the cochlea more likely to be damaged by noise. They cite a study by Rees (84) that showed that preterm infants born at less than 27 weeks who received aminoglycosides for 7 days or more while exposed to noise levels of greater than 80 dB for greater than 30 minutes produced by mechanical ventilation had a high probability (68%) of developing hearing loss (85). This clearly requires further study.

Hyperbilirubinemia is a well-recognized cause of hearing loss in newborns, and more recently it has been associated with auditory dyssynchrony. The 2007 JCIH guidelines list hyperbilirubinemia that requires exchange transfusion as a risk factor for the development of hearing loss. However, a study by Oh et al. (86) suggested that in VLBW infants even a moderate elevation of bilirubin may be related to poorer neurodevelopmental outcomes and hearing loss (86). A subsequent NEJM study by Morris et al. (87) assessing aggressive versus conservative phototherapy in VLBW infants showed that infants with even modestly elevated levels of bilirubin had less hearing loss when aggressive phototherapy was utilized, and in fact the aggressively managed group had better overall neurodevelopmental outcome (87). This raises the question of what level of bilirubin (bound or unbound, conjugated or unconjugated) should be considered a risk factor for the development of hearing loss, especially in relation to gestational age and weight, the presence or absence of sepsis or hypoxia, and other contributing factors.

Auditory neuropathy spectrum disorder (auditory dyssynchrony) is being increasingly identified in newborns who fail their hearing screening. A high percentage of these babies have a history of VLBW, early gestational age, hyperbilirubinemia, and sepsis. Because many of the studies assessing hearing loss in the NICU are observational, it is difficult to assign cause and effect. However, a recent study by Saluja et al. (88) found auditory dyssynchrony as the only manifestation of acute bilirubin-induced neurotoxicity in late preterm and term infants. The level of hyperbilirubinemia and the optimal management, especially in VLBW babies with complicated clinical pictures, remains uncertain (88).

Middle and Inner Ear Structural Anomalies

Although this chapter focuses primarily on inner ear pathology related to hearing loss, it is important to recognize that structural anomalies resulting in hearing loss can occur at any stage in the embryogenesis of these structures, with a resulting hearing loss that is conductive, mixed, or sensorineural. External auditory canal atresia is usually associated with various degrees of microtia and middle-ear abnormalities, and with improved imaging, an increasing number of these patients are also found to have inner ear anomalies. Congenital stapes disorders are often related to aberrant facial nerve development. During the crucial time period of 6 weeks postfertilization, if the facial nerve is displaced anteriorly, the stapes will be prevented from coming in contact with the otic capsule, resulting in a malformed stapes. Vrabec and Lin (89) reported a 13% incidence of facial palsy and a 22% incidence of inner ear anomalies in 118 pediatric patients with aural atresia. All of the facial paralysis patients also had inner ear abnormalities, with some children having unilateral facial palsy but bilateral inner ear anomalies (89).

Hundreds of syndromes have hearing loss associated with middle and/or inner ear anomalies as one of the features. Many of the patients will present with mixed, or occasionally purely conductive, hearing loss. Mutations in the X-linked POU3F4 gene are associated with dilatation of the internal auditory canal and a range of temporal bone anomalies that include stapes fixation and dysplasia of the cochlea and semicircular canals (SCCs). These patients, who are otherwise nonsyndromic, present with a congenital and subsequently progressive mixed hearing loss. The surgeon may encounter a fixed stapes and perilymphatic gusher at the time of cochlear implant or other middle-ear surgery (90).

Although hundreds of syndromes have both middle and inner ear anomalies, two syndromes for which the hearing loss is a defining feature include CHARGE and branchio-oto-renal (BOR) syndromes. Seventy percent of CHARGE patients have mutations in the CHD7 gene, with a much smaller number having mutations in the SEMA3E gene, while BOR patients have mutations in the EYA1 and SIX5 genes, and mutations in SIX1 in patients with branchio-otic syndrome. Both syndromes have characteristic middle and inner ear anomalies and may present with conductive, sensorineural, or mixed hearing losses. Findings in BOR include a hypoplastic apical turn of the cochlea; facial nerve canal deviated to the medial side of the cochlea; a funnel-shaped internal auditory canal; a patulous eustachian tube; hypoplasia of the horizontal, superior, and posterior SCCs; and hypoplasia/dysplasia of the malleus and incus (91,92). In 2006, Morimoto et al. reported temporal bone imaging in 13 patients (26 ears) with a clinical diagnosis of CHARGE association; none had testing for CHD7 mutations. Middle-ear findings included 21/26 ears with small middle-ear cavities and 23/26 with dysplastic

ossicles. All cases demonstrated absent SCCs. Twenty of twenty-six (77%) ears demonstrated cochlear aperture atresia; four were found to lack a cochlear nerve on MRI. Twenty-one of twenty-six (81%) had cochlear dysplasia, six had round window aplasia, and three had round window hypoplasia. Twenty-one of twenty-six (81%) had oval window atresia or aplasia, and fifteen had hypoplastic or dysplastic vestibules. Additional findings included enlarged or anomalous vestibular aqueducts, and 23/26 facial nerve canals had an anomalous course (93).

Congenital perilymphatic fistula (PLF) has been associated with a Mondini deformity of the cochlea (94). Sites of fistula include the oval window, fundus of the modiolus, fissulae ante fenestrum, and round window. Patients with congenital PLF are at increased risk for bacterial meningitis (95). Symptoms of PLF include fluctuating or progressive SNHL or mixed hearing loss and intermittent unsteadiness or vertigo.

Anomalies of the Inner Ear

In patients with unilateral or bilateral SNHL or mixed hearing loss, inner ear anomalies are demonstrated by either CT and/or MRI of the temporal bones 20% to 39% of the time (96). Histopathologically, the hearing losses can involve the membranous and/or bony components of the labyrinth. The membranous labyrinth consists of the cochlear duct, semicircular ducts, utricle, saccule and endolymphatic duct, and sac. The bony labyrinth envelopes the membranous labyrinth and consists of the cochlea, the three SCCs, the vestibule, and the vestibular aqueduct.

Currently, the most common classification system of labyrinthine malformations is that introduced by Jackler et al. (97) in 1987. This system proposed classification of inner ear anomalies based on their likely occurrence in embryogenesis. Based on radiographic and histologic studies, the most significant events in embryologic development of the labyrinth were noted to occur between the fourth and eighth weeks of gestation with further maturation occurring up until birth and possibly beyond. Most inner ear malformations resemble histologic sections of the inner ear taken at different points in development, leading Jackler et al. (97) to conclude that malformations arise as a result of arrest in development at a specific point in embryogenesis. Malformations are divided into either membranous alone or both membranous and osseous anomalies. While their development occurs during the same time period, the development of the SCCs and cochlea are dependent on many genes, several of which are specific for either the cochlea or the vestibular apparatus. Therefore, isolated arrest in the development of each of these structures can occur. While the Jackler classification system cannot account for the entire constellation of inner ear anomalies, it provides a framework when relating anomalies to embryogenesis. Further information will be obtained as imaging techniques improve and the molecular biology of the cochlear and vestibular systems is elucidated.

As the ability to radiographically evaluate patients with SNHL has improved, the classification of inner ear anomalies has been modified. Incomplete partition of the cochlea (*Mondini malformation*) is the most common cochlear malformation seen on imaging, accounting for up to one half of all bony cochlear anomalies. It is frequently associated with the presence of an EVA. In 1791, Mondini described a specific cochlear malformation of incomplete cochlear partition (hypoplastic modiolus); short cochlear duct with a flat cochlea; auditory and vestibular organs that were immature; a dilated vestibule; SCCs that were wide, small, or missing; an endolymphatic sac that was bulbous; and a large vestibular aqueduct (LVA). Instead of its usual 2½ turns, the cochlea has 1½ turns with an absent interscalar septum between the middle and apical turn. Embryologically, this corresponds to arrest in development during the seventh week of gestation. The "pseudo-Mondini" malformation likely occurs earlier in the seventh week than the more developed Mondini malformation.

With the advent of widespread newborn hearing screening and routine recommendations for cochlear implantation, hearing aid usage, bone-anchored hearing aids, and early intervention services for language and speech, the need for better definition of inner ear anatomy for planning and prognosis has increased. Additionally, routine use of high-resolution CT and MRI temporal bone imaging has shown increasingly detailed anatomy of both the bony and membranous labyrinth. A new classification, published by Sennaroglu and Saatci (98) in 2002, further classified the Mondini abnormality into two distinct entities. The intracochlear partition type II (IP-II, "Mondini") cochlea has 1.5 turns (in which the middle and apical turns coalesce to form a cystic apex) accompanied by a dilated vestibule and EVA. The intracochlear partition type I (IP-1) malformation has an empty, cystic cochlea and vestibule without an EVA. The degree of hearing loss in the true Mondini malformation is typically less severe than in the cystic cochleovestibular malformation (98,99).

Stapes footplate anomalies and modiolar defects have also been found in association with Mondini malformation, predisposing these patients to the risk of PLF and meningitis. Seventh nerve anomalies are typically found when stapes anomalies are present, with displacement of the second genu anteriorly and inferiorly (100). Mondini malformations have been associated with several syndromes including Waardenburg, DiGeorge, and Pendred. Pendrin gene defects have also been seen in nonsyndromic SNHL cases associated with EVA (DFNB4) (101).

Similar to Mondini's description of EVA, other inner ear anomalies were first described in temporal bone specimens. The Michel anomaly, complete aplasia of all inner ear structures, reflects arrest of inner ear development prior to the fourth week of gestation. Corresponding CT imaging shows an absence of inner ear structures. Rarely,

complete aplasia can be confused with labyrinthitis ossificans, although a combination of CT and MRI should be able to differentiate one from the other (102). Clinically, Michel aplasia has been associated with thalidomide exposure, anencephaly, and Klippel-Feil syndrome. As expected, patients with Michel anomaly present with profound SNHL. Although these patients are not candidates for cochlear implantation, they may be candidates for brain stem implantation in the future (103).

Failure of the cochlear and vestibular apparatus to develop early in the fourth week of gestation results in a common cavity deformity, where the membranous labyrinth is poorly differentiated and situated in a large common cavity (104). The labyrinthine segment of the facial nerve can be displaced anteromedially. Hearing loss in patients with a common cavity is generally in the severe to profound range. Although cochlear implantation has been successfully performed on these patients, results vary depending on degree of membranous and neural development, including auditory nerve development. Surgically, cerebrospinal fluid (CSF) or perilymphatic leaks are common and need to be addressed with the patient and parents preoperatively (100).

Failure in labyrinth development in the fifth week of gestation results in cochlear aplasia. This is a rare anomaly where the cochlea fails to develop and the vestibule and SCCs are present although abnormal. These patients present with profound SNHL and implantation may be precluded by lack of an auditory nerve (105).

Arrest of development in the sixth week of gestation results in cochlear hypoplasia. On CT imaging, the cochlea may appear round and undeveloped, usually measuring 6 mm in height compared to a normal cochlea of 10 to 12 mm. In severe cases, the labyrinthine segment of the facial nerve can be displaced anteromedially. These patients present with various degrees of hearing loss depending on the exact time of arrest within the sixth week. Patients who have greater differentiation of the membranous labyrinth and more neuroepithelial elements have better hearing. Hearing results following cochlear implantation also depend on the degree of membranous differentiation.

The LVA, also known as EVA is the most common inner ear anomaly seen on temporal bone imaging in patients with SNHL or mixed hearing loss. While it is agreed to be the most common radiographic finding, the radiographic definition of EVA is evolving. Using fresh temporal bone specimens and tomography, it was described by Valvassori and Clemis (106) as an aqueduct that measures 1.5 mm or greater at the midpoint between its internal and external aperture. They also noted an enlarged vestibule, enlarged vestibule and SCC, enlarged vestibule and hypoplastic cochlea, or hypoplastic cochlea in many of the specimens. They further suspected that there were probably other abnormalities below the level of resolution of the tomography (106).

Harnsberger et al. (107), in 1995, suggested that 0.1 to 1.4 mm at the midpoint of the endolymphatic duct was normal on CT. Other authors have defined it as a diameter greater than 2 mm, with the measurement taken at its widest point or at the external aperture (108,109). Further refinement of these measurements was published by Vijayasekaran et al. (110), in 2007, using ≥1.0 mm at the midpoint and ≥2.0 mm at the operculum. A large endolymphatic sac, with or without the presence of LVA, is also associated with hearing loss. While LVA can be detected with both CT and MRI, the entire endolymphatic sac can only be seen with MRI (111).

LVA is found in association with cochlear anomalies, most commonly incomplete partition. Cases of EVA in isolation have been reported (112). One argument in favor of the isolated LVA is based on the embryogenesis of the vestibular aqueduct. A histologic study by Pyle (109) demonstrated progressive growth of the aqueduct throughout gestation while growth of the remaining labyrinth was virtually complete by the second trimester. Therefore, an isolated LVA could occur following normal development of the cochlea and SCCs. However, opposing arguments have been raised, proposing developmental arrest at 5 weeks as the etiology of LVA (100).

LVA is often associated with Pendred syndrome. Pendred syndrome, characterized by goiter and SNHL, is the most common syndrome with associated SNHL, accounting for 10% of patients with syndromic hearing loss. Mutations in the Pendrin gene (PDS, SLC26A4) cause Pendred syndrome but are also responsible for a nonsyndromic form of recessive SNHL, DFNB4. In the nonsyndromic form, the patients have temporal bone anomalies without associated thyroid goiter or detectable abnormalities of thyroid function. The findings of LVA can also be found in other syndromes, including X-linked mixed deafness with gusher (DFN3, POU3F4), BOR syndrome (associated with mutations in the EYA1 and SIX1 genes), and Waardenburg syndrome (113). In each syndrome, associated cochlear malformations are common.

The clinical presentation of the hearing loss in patients with EVA is variable. The hearing loss may be sensorineural, mixed, or occasionally purely conductive. Not infrequently, patients have normal hearing at birth and experience progressive or fluctuating hearing loss. Sudden hearing loss is also seen, either spontaneously or with even mild head trauma. Approximately 30% to 50% of patients will experience worsening and/or fluctuation of their hearing over time. Proposed mechanisms for hearing loss include membrane rupture causing a change in electrolyte homeostasis versus increased pressure forcing CSF through the cochlear duct (114).

Hearing preservation procedures in patients with EVA have been attempted through endolymphatic sac shunts, occlusion, or decompression. However, the results were disappointing with 50% to 100% of the patients developing worse hearing loss following the procedure (115). As a result, surgical intervention is not recommended. Currently, patients are advised to avoid activities that have high risk for head trauma or pressure changes, such as

flying or diving, although the actual incidence of a permanent change in the hearing from these activities remains unknown.

Vestibular Anomalies

The most common abnormality of the vestibular apparatus is aplasia or dysplasia of the lateral SCC. Lateral SCC dysplasia is reported by some authors to be the second most common osseous inner ear anomaly after LVA (116,117). The lateral SCC is more often involved due to its later development during embryonic development than the superior and posterior canals. Vestibular malformations frequently present in association with cochlear malformations and LVAs as their development occurs during the same weeks of gestation.

Patients with lateral SCC dysplasia may present with sensorineural, mixed, or conductive hearing loss. It occurs in isolation or associated with a syndrome. A commonly associated syndrome is CHARGE syndrome. CHARGE syndrome has characteristic inner ear findings including SCC aplasia in association with a stenotic cochlear aperture, underdeveloped vestibule, and incomplete partition of the cochlea. Children with trisomy 21 often have abnormal middle and inner ear structures, notably abnormalities of the SCC and a small bony island of the lateral SCC, smaller middle-ear space, and ossicular abnormalities (118).

Membranous Anomalies

Membranous labyrinthine anomalies occur in isolation and in combination with all bony labyrinthine anomalies. They account for a large percentage of patients with SNHL but because of limitations in imaging can only be inferred without histologic sectioning. As previously mentioned, the membranous labyrinth is divided into two components, the pars superior and the pars inferior. The pars superior forms the SCCs, endolymphatic duct, and utricle, and the pars inferior becomes the saccule and cochlear duct. Anomalies can involve an isolated portion of the membranous labyrinth, one division, or the entire labyrinth.

Bing-Siebenmann Malformation (Cochleosaccular Dysplasia)

The Bing-Siebenmann malformation is an isolated membranous malformation characterized by membranous labyrinthine aplasia or dysplasia with a well-formed bony capsule. On histopathologic section, the cochlear duct has a poorly developed organ of Corti with an abnormal stria vascularis and collapse of Reissner membrane. The saccule and macula are also poorly developed. Clinically, patients with Bing-Siebenmann malformation have profound SNHL. This malformation has been seen in patients diagnosed with Usher syndrome and Jervell and Lange-Nielsen.

Scheibe Malformation

Scheibe malformation is the most common membranous inner ear malformation. It results from a defect in the development of the pars inferior resulting in a malformed organ of Corti and saccule. Histologically, there is a partial or complete aplasia of the organ of Corti and collapse of the cochlear duct. Clinically, the Scheibe malformation presents with severe to profound SNHL. It is most often associated with Usher syndrome but is also seen with Jervell and Lange-Nielsen, Refsum disease, Waardenburg syndrome, and trisomy 18. Inheritance in an autosomal recessive fashion with a gene defect on chromosome 1q32 has also been demonstrated.

Alexander Malformation

The least severe membranous malformation was described by Alexander in 1904. It involves an otherwise normal labyrinth with the exception of a dysplastic basal turn of the cochlea. The Alexander malformation is found in association with hereditary high-frequency SNHL.

The Overall Evaluation of Neonatal and Childhood Onset Hearing Loss

The diagnostic evaluation of hearing loss in newborns and young children is in rapid evolution, and several algorithms have been proposed for this purpose. Which diagnostic tests and in which order they are obtained depends on the age of the child, history and physical examination, family history, the degree and laterality of hearing loss, what the most likely etiologies are given the patient's presentation, and what the proposed interventions might be. In addition, insurance coverage for certain studies, parental understanding (especially of any proposed genetic studies), whether sedation is needed, and which studies are available locally versus away from the hometown or institution may all play a role in the diagnostic evaluation. Lin et al. (119) recently reported on the diagnostic yield of several studies in 270 children with severe to profound SNHL evaluated between 2002 and 2009. They reviewed temporal bone MRI and CT, renal ultrasound, electrocardiogram (ECG), fluorescent treponemal antibody absorption test for syphilis (FTA), connexin 26 sequencing, genetic consultation, and ophthalmologic evaluation. MRI revealed abnormalities in 24% of the children, CT in 18%, and biallelic connexin 26 (GJB2) mutations were present in 15%. The yield of the other tests was renal ultrasound (4%), ECG (long QT in 1%), FTA (0.5%), genetics evaluation (25%), and ophthalmologic consultation (8%). Nearly all the children with biallelic GJB2 mutations had nonsyndromic SNHL, and several had passed a newborn hearing screen. Although the percentage yield for CT and MRI was similar, they did not always find the same abnormalities; EVA was occasionally picked up by MRI and not by CT, and vice versa. MRI of the brain found brain malformations and indications of congenital infections (e.g., CMV),

which CT of the temporal bones did not. Ophthalmology evaluations revealed myopia, coloboma (in children with CHARGE association), and two with retinitis pigmentosa eventually found to have Usher syndrome. All children with hearing loss are visual learners, so even finding out that they need eyeglasses is useful information, and if they have less common but other important findings that may yield an additional diagnosis that obviously benefits the patient.

The diagnostic yield for specific tests in the Lin et al. (119) study is in good agreement with others, including Preciado et al. (120). Testing for diagnoses that are treatable, such as congenital CMV, or dangerous if missed, such as long QT in children with bilateral severe to profound SNHL, should always be considered. Many studies commonly performed in the past to diagnose genetic causes may now be better evaluated using actual genetic testing. An example of this are mutations in the SLC26A4 (PDS) gene associated with bilateral EVA (nonsyndromic EVA, DFNB4) and, in some cases, thyroid dysfunction (the full Pendred syndrome). A second is Usher syndrome, where genetic testing may be positive in the presence of a normal routine eye examination, especially in young children (121,122). CMV was not routinely tested in the Lin et al. (119) or most other studies. However, since congenital CMV and toxoplasmosis are treatable, testing for CMV in infants would be a reasonable place to start in neonates and very young infants (123). In addition, although CS is uncommon, it is another treatable cause, so testing would be justified if clinically suspected. In addition, patients with biallelic GJB2 mutations seldom have anatomic inner ear abnormalities, so if initial imaging is normal, then mutations in GJB2 would be a stronger consideration, while if the imaging is abnormal, GJB2 would be less likely. For some of the more common causes, very occasionally, there may be overlap in the same patient. For example, babies with congenital CMV may also have EVA or GJB2 mutations. Therefore, if the presentation does not completely fit the initial diagnosis, especially as the patient is followed over time, further evaluation for additional causes of hearing loss should be considered. The overall diagnostic yield for these studies taken together (especially imaging, genetics, and CMV) is 50% to 60% and is likely to improve with better genetic testing, higher-resolution imaging, and increased awareness of the incidence of congenital CMV.

SUMMARY

Pediatric hearing loss is common and, with the advent of newborn hearing screening, diagnosed at increasingly younger ages. The identification of a definite etiology can aid in prognosis and management. The yield of diagnostic studies has increased given accurate testing for, and awareness of the frequency of, congenital CMV, anatomic anomalies of the inner ear, and genetic causes. A methodical approach to diagnostic studies, based on laterality and degree of hearing loss, history and physical examination, family history, and overall clinical presentation, will frequently yield an etiology.

HIGHLIGHTS

- Hearing loss is the most common congenital sensory impairment.
- Even if an infant passes a newborn hearing screen, it does not always mean the baby does not have a hearing loss or will not develop hearing loss. If hearing loss is later confirmed, it may be because the hearing loss was mild, and the baby passed the screen, or in a frequency range not picked up by the screen; the hearing loss has worsened; the baby had an OAE screen and has auditory dyssynchrony; or the screen was a false negative.
- According to a recent NHANES study, by the age of 12 to 19 years, the rate for any degree or laterality of hearing loss is 19.5%.
- Hearing screening should be performed in all newborns and may consist of ABR, OAE, or a combination of both
- The most common causes of congenital hearing loss in healthy term newborns are related to CMV, structural middle and inner ear abnormalities, and genetics.
- Later onset hearing loss may be due to worsening of a congenital cause, such as congenital CMV or preexisting structural abnormality such as EVA, or to a newly acquired cause, such as noise exposure, head trauma, chemotherapy or meningitis.
- Prenatal exposure to CMV is the most common congenital viral infection and currently the most common viral cause of congenital SNHL. The prevalence of congenital CMV infection is approximately 0.4% to 2.3% of all newborns. If the mother has a primary CMV infection during pregnancy, there is a 40% chance that the infant will become infected, and if she has a reactivation infection, there is about a 2% chance.
- In patients with unilateral or bilateral SNHL, mixed hearing loss, or uncommonly conductive hearing loss alone, inner ear anomalies are demonstrated by CT and/or MRI of the temporal bones 20% to 39% of the time. The most common anomalies seen include cochlear dysplasia, enlarged vestibular aqueduct/endolymphatic sac, cochlear stenosis, and lateral SCC dysplasia.
- Some structural anomalies are associated with certain genetic abnormalities or syndromes. These include Pendred syndrome, CHARGE association, BOR syndrome, and Waardenburg syndrome.

- Ophthalmology evaluations in children with hearing loss are very important, as all children are visual learners. However, a normal routine eye exam, especially in an infant or young child, does not rule out retinitis pigmentosa and Usher syndrome. If Usher syndrome is a serious consideration, evaluation of the retina, with ERG as the gold standard, should be considered. Clinical genetic testing for most Usher genes is also available, and a definite diagnosis of Usher syndrome can now be made even in early infancy.

Genetic Hearing Loss

102

John Greinwald *Catherine Hart*

Hearing impairment is the most common sensory deficit. It occurs in 2 to 3 per 1,000 live births and affects approximately 28 million Americans (1). It can be congenital or acquired, developing any time during infancy, childhood, or adulthood. Of children younger than 18 years of age, 5% have a hearing impairment, and that incidence increases to 40% to 50% by age 75. Among school-aged children, 2% have a hearing loss that interferes with educational achievement.

Most cases of hearing loss are attributed to nongenetic causes (e.g., middle-ear fluid). Advances in technology and mass screening programs, however, have resulted in an ongoing increase in the identification of specific heritable forms of deafness, most of which are expressed as sensorineural losses. Heritable hearing loss can be transmitted through various patterns of inheritance. Most authors attribute 75% to 80% of genetic deafness to autosomal recessive patterns and 18% to 20% to autosomal dominant patterns. The remainder are classified as X-linked or mitochondrial. Additionally, deafness can present as an isolated finding (nonsyndromic) or can be associated with other pathologic findings (syndromic) such as craniofacial anomalies.

This chapter presents an overview of heritable hearing loss within the framework of these basic genetic principles. We discuss a number of genes that are linked to a wide spectrum of hearing disorders and briefly describe the relevance of genetic advances to case management.

BASIC GENETIC PRINCIPLES

Human genes are molecular codes for inherited factors. Genes are arranged linearly on 23 pairs of chromosomes. These chromosomes consist of 22 pairs of autosomes and 1 pair of sex chromosomes, comprising a total of 46 chromosomes. Males have an X and a Y pair of sex chromosomes, whereas females have two X chromosomes. The location of a gene on a chromosome is termed a locus. Each chromosome pair carries a distinctive set of gene loci, and a given gene can have several alternative codes, which are referred to as alleles. The actual genetic code (genotype) for a specific trait consists of either two identical alleles (homozygous) or two disparate alleles (heterozygous). The physical manifestation of a trait, referred to as the phenotype, is determined by which alleles are present and how they interact. An allele is considered dominant if its presence results in a specific phenotype. It is considered autosomal recessive if both alleles are required for the expression of its phenotype. An X-linked recessive gene is present in only one allele (hemizygous) in males because the Y chromosome does not carry an allele complementary to the X chromosome. A specific DNA base pair change at a specific allele is considered a truncating or nontruncating mutation.

A nontruncating (or missense) mutation alters the codon resulting in an altered amino acid product. A truncating (or nonsense) mutation results in a nonfunctional protein due to premature termination of transcription. Truncating mutations can also occur due to mutations at the exon splice sites, which result in nonfunctional protein production.

Dominant traits are transmitted in a vertical fashion from one generation to another. A 50% chance exists that an affected heterozygous individual will transmit the abnormal gene to offspring. Penetrance is the ability of a gene to manifest any of the phenotypic characteristics related to that gene. In some dominant disorders, not all persons carrying the affected gene display the disease phenotype. This occurrence is called incomplete penetrance. Dominant disorders also can have variable expressivity, whereby family members present with different manifestations of the affected gene. It is thus presumed that environmental influences or interaction with other genes can modify phenotypic expression.

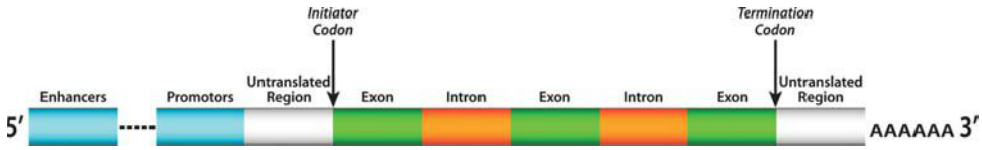

Figure 102.1 Basic gene structure.

In the absence of consanguinity, an autosomal recessive trait is usually seen in an offspring in small nuclear families. The offspring of heterozygous (i.e., carrier) parents have a 25% risk of being affected. Occasionally, being heterozygous for two different genes (double heterozygous) can cause a condition. An X-linked recessive trait can lack phenotypic expression if it is carried by a heterozygous female, but male offspring of this female would have a 50% chance of inheriting the gene. Expression of the gene would then occur because of the absence of a second X chromosome. A female offspring of an X-linked female carrier has a 50% risk of being a carrier of such a trait. Because males inherit their father's Y chromosome and not his X-linked recessive gene, they are unaffected and do not become carriers. In contrast, females inherit their father's X-linked recessive trait and, as such, do become carriers of the affected gene.

Heritable disorders that are caused by abnormalities at the chromosomal level and involve extra or absent chromosomal material are characterized by developmental delays and varied congenital anomalies, except when they involve the sex chromosomes. The nature and severity of the resultant disorders depend on the quantity and origin of the chromosomal material involved. In persons with trisomy, three copies of an entire chromosome are present. Trisomy 21 (Down syndrome) is the least severe autosomal trisomy. Trisomy 13 (Patau syndrome) and trisomy 18 (Edwards syndrome) are less common but more severe. Other autosomal types of trisomy usually are lethal. In the condition known as monosomy, which is also lethal, only one chromosome rather than a pair is present. Embryos with sex chromosome abnormalities are quite viable, with the exception of a conceptus with only a Y chromosome. Persons with one extra X or Y chromosome or with only one X chromosome have mild clinical features such as seen in Klinefelter syndrome (47,XYY or 47,XXY) and Turner syndrome (45,X).

It is known that disparate genotypes can produce a similar phenotype. This phenomenon, which is referred to as genetic heterogeneity, often makes it difficult to identify causative genes. In nonsyndromic hearing loss, gene identification is difficult in that there is a high degree of heterogeneity and an absence of features that clearly define clinical subtypes. In syndromic hearing loss, however, distinct subtypes as well as interfamilial differences assist in the identification of these genes. The identification of autosomal recessive nonsyndromic hearing loss genes is facilitated through the study of both inbred and isolated populations, which reduce genetic heterogeneity. Studies of large families (kindreds) can facilitate the identification of autosomal dominant hearing loss genes.

A detailed description of the process involved in gene identification is beyond the scope of this chapter. In brief, however, this process entails the following three steps: A gene is first localized to a specific chromosomal region. Physical mapping techniques are then used to isolate DNA from that region. Through the efforts of the Human Genome Project, nearly all of the 30,000 human genes have been mapped, thereby allowing for the bioinformatic identification of candidate genes. Step three involves sequencing analysis of candidate genes to identify the specific mutation associated with a particular disease.

Each gene generally consists of DNA that codes for (a) the actual protein(s) (exons); (b) interspersed areas between exons, which are called introns; and (c) untranslated regulatory regions before and after the exons, which are respectively referred to as upstream and downstream (Fig. 102.1). The upstream untranslated region has specific areas of DNA that are bound by regulatory proteins. These areas regulate the function of the gene, and this region is called the promoter. Occasionally, one common promoter may exist for several genes, which is called a locus control region.

AUTOSOMAL RECESSIVE DISORDERS

Most genetic hearing disorders are transmitted by an autosomal recessive mode of inheritance, and of the hearing disorders presenting in childhood, approximately 80% are inherited recessively. In most patients, hearing loss is nonsyndromic, but 10% to 20% of patients display syndromic disorders. The identification of recessive syndromes involving hearing loss, thus, necessitates a diligent search for other syndromic components. Because of the asymptomatic status of heterozygous carriers of a recessive gene and the 25% inheritance risk, it is often difficult to distinguish between nongenetic disorders and those that are recessively inherited. In both clinical situations, a single affected child generally presents in a family with no known history of hearing loss.

Nonsyndromic Recessive Disorders

To date, linkage studies have identified at least 85 loci for autosomal recessive nonsyndromic hearing loss (ARNSHL) (2). These loci are given the prefix DFNB; DFN signifies deafness, whereas B signifies a recessive mode of inheritance. Thirty seven causative ARNSHL genes have been identified (Table 102.1). DFNB1 accounts for about one half of all ARNSHL and, as such, is among the most active areas of clinical research. As implied by its designation,

TABLE 102.1 SELECTED GENETIC DEFECTS ASSOCIATED WITH HEARING IMPAIRMENT

Gene (Protein)	Locus	Mode of Inheritance or Syndrome	Phenotype
CDH23(cadherin 23)	DFNB12	ARNSHL	SNHL
	Usher 1C	AR syndromic	Congenital hearing loss, retinitis pigmentosa, and variable vestibular areflexia
COCH (cochlin)	DFNA9	ADNSHL	Onset of hearing loss occurs between ages 20–30; profound at high frequencies and variable progression to anacusis by age 40–50. Variable vestibular dysfunction
COL2A1 (collagen 2A1)	Stickler type 1	AD syndromic	Robin sequence, myopia, joint degeneration, variable degree of hearing loss
COL11A1(collagen 11A1)	Stickler type 2		
COLL11A2(collagen 11A2)	Stickler type 3		Stickler type 1 phenotype without ocular problems
COL4A3(collagen 4A3)	Alport	X-linked	Progressive high-frequency SNHL, nephritis
COL4A4 (collagen 4A4)		AR syndromic	
COL4A5 (collagen 4A5)		AD syndromic	
GJB2 (connexin 26)	DFNA3A	ADNSHL	Severe to profound SNHL
	DFNB1A	ARNSHL	Mild to profound SNHL
GJB6 (connexin 30)	DFNB1B	ARNSHL	Severe to profound SNHL
	DFNA3B	ADNSHL	High frequency to profound SNHL
DDP (deafness or dystonia peptide)	DDP (previously called DFN1)	X-linked syndromic	Early onset deafness with mental retardation
DIAPH1 (diaphanous)	DFNA1	ADNSHL	Fully penetrant progressive, low-frequency SNHL
EDNRB (endothelin receptor)	Waardenburg type 4	AR syndromic	WS with Hirschsprung disease
EYA1 (eyes absent 1)	Branchio-oto-renal	AD syndromic	Conductive, sensorineural, or mixed hearing loss with branchial remnants and renal anomalies
KVLQT1 (potassium-gated voltage channels)	Jervell and Lange-Nielsen	AR syndromic	Severe to profound SNHL, syncope, prolonged QT
KCNE1 (potassium channel voltage-gated, risk-related subfamily member 1)			
MITF (microphthalmia-associated transcription factor)	Waardenburg type 2	AD syndromic	Same as type 1 without dystopia canthorum
MYO7A (myosin 7A)	DFNB2	ARNSHL	Progressive SNHL with variable vestibular and ocular findings
	DFNA11	ADNSHL	Moderate SNHL
	Usher 1B	AR syndromic	Profound congenital deafness, vestibular areflexia, and progressive retinitis pigmentosa
NDP (norrin)	Norrie	X-linked syndromic	Ocular symptoms, progressive SNHL, and mental retardation
OTOF (otoferlin)	DFNB9	ARNSHL	Severe to profound SNHL
PAX3 (paired box gene 3)	Waardenburg type 1	AD syndromic	White forelock, heterochromia iridis, SNHL, and dystopia canthorum
SLC26A4 (pendrin)	DFNB4	ARNSHL	Enlarged vestibular aqueduct, euthyroid goiter
	Pendred	AR syndromic	Mondini dysplasia and SNHL
POU3F4 (POU domain 3, transcription factor 4)	DFN 3	X-linked	Stapes fixation
POU4F3 (POU domain 4, transcription factor 3)	DFNA15	ADNSHL	Progressive hearing loss
TCOF1 (treacle)	Treacher Collins	AD syndromic	Lower eyelid coloboma, micrognathia, microglossia, zygomatic arch hypoplasia, macrostomia, hearing loss
TECTA (α-tectorin)	DFNA8/12	ADNSHL	Prelingual severe to profound SNHL
	DFNB21	ARNSHL	
USH1C (USH1C)	Usher 1C	AR syndromic	Profound congenital deafness, vestibular areflexia, and progressive retinitis pigmentosa
USH2A (USH2A)	Usher2A	AR syndromic	Congenital sloping hearing loss, normal vestibular function, and progressive retinitis pigmentosa
MTRNR1	12rRNA	mitochondrial	Mild to severe hearing loss, usually associated with aminoglycoside
MTTS1	$tRNA^{ser\ (UCN)}$	mitochondrial	Mild to severe hearing loss, can be progressive

AD syndromic, autosomal dominant syndromic; ADNSHL, autosomal dominant nonsyndromic hearing loss; AR syndromic; autosomal recessive syndromic; ARNSHL, autosomal recessive nonsyndromic hearing loss; SNHL, sensorineural hearing loss.

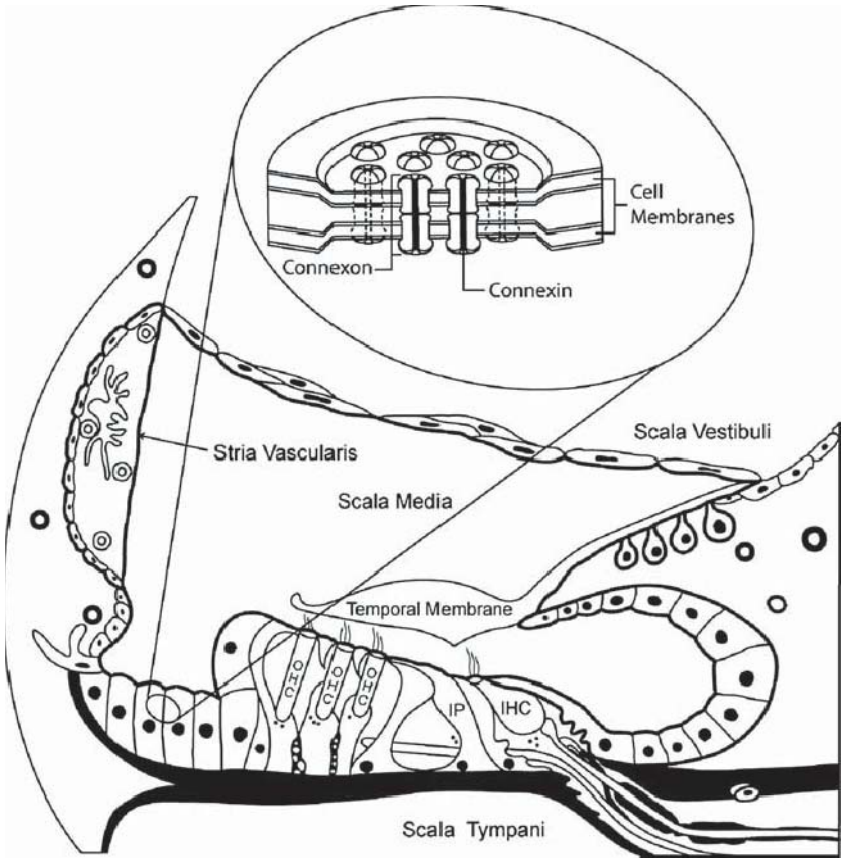

Figure 102.2 Location of gap junctions within the supporting cells of the organ of Corti. Six connexins comprise a connexon. Connexons form gap junctions, which function as intracellular channels.

DFNB1 was the earliest autosomal recessive gene locus to be successfully mapped and characterized. The gene at the DFNB1 locus is gap junction beta 2 (*GJB2*), which produces a protein called connexin 26 (1). Connexins comprise a family of gap junction proteins that function as intercellular channels. These channels allow ions and low molecular weight molecules to travel from cell to cell (Fig. 102.2). The supporting cells of the organ of Corti express several gap junction proteins, including connexin 26. Although the function of connexin 26 in the inner ear has not been conclusively determined, it is thought to be involved in potassium recycling. In the normal ear, a sound stimulus causes depolarization of hair cells, which is mediated by the influx of potassium ions. These ions are thought to transverse through connexin molecules back to the stria vascularis. From the stria vascularis, ions are actively pumped back into the endolymph to reset its electrical gradient (Fig. 102.2).

DFNB1 is estimated to cause up to 50% of all ARNSHL in many populations. Of patients presenting with hearing impairment of 70 dB or greater, nearly 40% have DFNB1; of those with a mild to moderate hearing loss, only 10% to 15% have this gene (3,4). *GJB2* mutations have been found in patients from many different ethnic backgrounds, and specific mutations vary with patient ethnicity. The deletion of a guanine at nucleotide position 35 of the gene (35delG) is one of the most common mutations that results in autosomal recessive hearing impairment, particularly in patients of European descent. The carrier frequency for the 35delG deletion in Europe is 1 in 50. A deletion of a thymine at position 167 (167delT) is often present in the Ashkenazi Jewish population, with a carrier frequency of 1 in 25. A 235delC mutation occurs more frequently in Asians. Among the white population in the United States, the frequency of heterozygous carriers of mutations in *GJB2* is approximately 1 in 40. This carrier frequency is almost as common as that in cystic fibrosis, which has a carrier frequency of approximately 1 in 24. The high frequency of mutations and the small size of this gene make screening and molecular genetic diagnosis feasible.

Additionally, a unique genetic mutation has been found in the *GJB6* gene. This mutation appears to present in carriers of *GJB2* mutations (double heterozygote state). A large deletion (170 to 340 kilobases [kb]) upstream and including the 5′ portion of the *GJB6* gene has been found to cause severe hearing loss (5). Interestingly, *GJB2* and *GJB6* are located in close proximity on chromosome 13, and this deletion may interfere with a common promoter element for the two genes (locus control region). Approximately 10% of patients with hearing loss who have one abnormal *GJB2* allele also have the *GJB6* deletion (6).

GJB2 mutations can create altered protein expression, subcellular localization, or abnormal functionality of the connexin complex. *GJB2* mutations cause a wide range of

hearing loss phenotypes, ranging from mild to profound hearing impairment. These mutations can be nontruncating or truncating. The type of mutation can produce varying levels of hearing loss. For example, a biallelic truncating mutation produces a severe to profound hearing loss in nearly all patients (e.g., 35delG/35delG). In contrast, the presence of one nontruncating mutation (e.g., V37I) commonly causes a milder form of hearing impairment (2).

The clinical significance of DFNB1 mutations lies in diagnostic evaluation and case management. Genetic testing is now routinely part of the algorithm in the evaluation of hearing loss (7). Genetic testing should be the first line of evaluation of children with bilateral ARNSHL of 60 dB or greater (Fig. 102.3). For those with unilateral or mild bilateral hearing impairment, genetic testing should be considered after temporal bone imaging is performed. If the imaging study is normal, genetic testing is then appropriate. If the imaging study demonstrates enlarged vestibular aqueduct or Mondini deformity, *SLC26A4* (Pendred) testing should be performed. New genetic platforms will allow rapid screening for multiple genes at one time (e.g., "Ear-gene," Cincinnati Children's Hospital Medical Center, Cincinnati, OH). Recent data have shown that gene chip platforms are highly accurate and will likely become instrumental in diagnostic evaluation of sensorineural hearing loss (SNHL) (8).

The prognosis for children with hearing loss related to *GJB2* is variable and has been shown to correlate with the genotype. This is particularly important in light of new hearing screening programs that are increasingly detecting hearing loss in very young children. Genetic information can assist in predicting the actual hearing phenotype, which is valuable considering the emphasis on early (age 12 months) cochlear implantation. For example, if a nontruncating mutation is present, a child would be more likely to have mild hearing loss. Conversely, the presence of biallelic truncating mutations in a child in whom an auditory brainstem response (ABR) test at 1 month of age showed severe hearing loss would lead the practitioners to recommend early aggressive treatment. A high likelihood would exist of recommending cochlear implantation to ensure the child's ability to communicate verbally. Interestingly, research indicates that patients with DFNB1-related hearing loss who meet criteria for cochlear implantation have better outcomes than those with congenital hearing loss from other causes (9). Such findings emphasize that genotype can have clinical significance, and further study aimed at elucidating this particular association is ongoing.

Most other ARNSHL genes have been identified from isolated consanguineous families, and the prevalence of mutations in these genes in the general population has yet to be determined. A technology now being developed (resequencing microarray), however, will enable the rapid reading of a large amount of DNA.

Another ARNSHL gene worthy of note is otoferlin (*OTOF*). This gene was originally found to be the cause of hearing loss in several isolated families (DFNB9) (Table 102.1). Although the function of *OTOF* is not certain, it is hypothesized that this gene is a calcium sensor involved in hair cell exocytosis (10,11). Research has shown that in some patients, *OTOF* is also responsible for auditory neuropathy (AN) (12). AN is a unique form

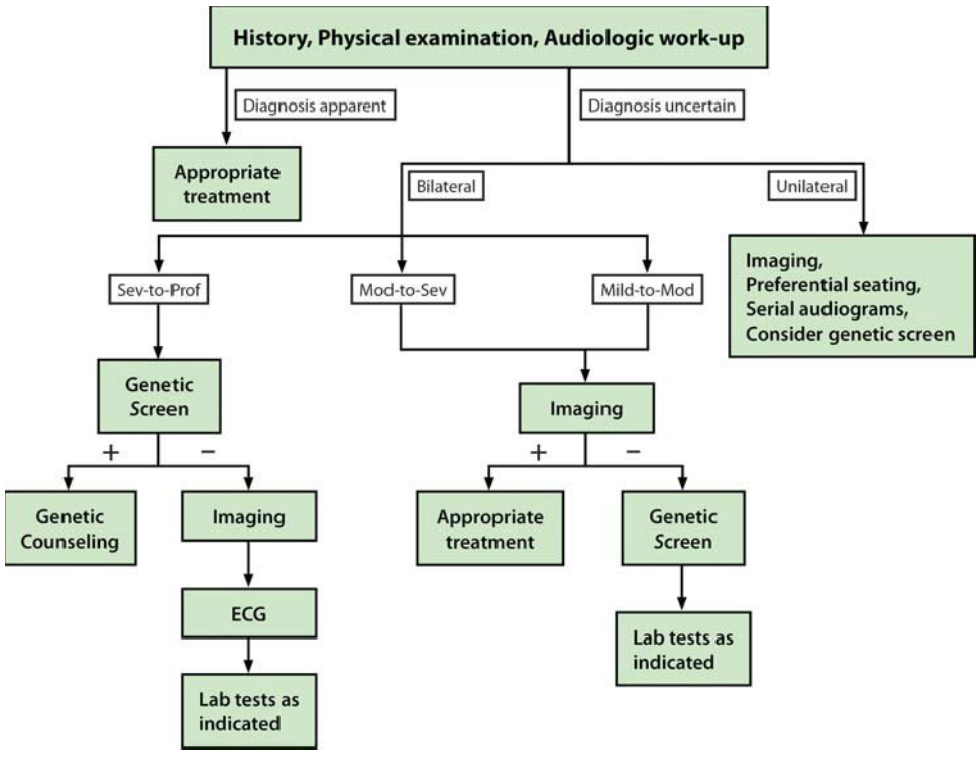

Figure 102.3 Algorithm for the diagnosis of genetic hearing disorders.

of SNHL characterized by absent ABR waveforms, present otoacoustic emissions, and variable behavioral thresholds. The prevalence of AN in patients with SNHL ranges from 0.5% to 15%. The etiology of AN is quite heterogenous with approximately 40% of cases having a genetic basis. It can be autosomal recessive, as in *OTOF*; autosomal dominant; X-linked; or syndromic. Some patients with AN also have other peripheral neuropathies or central nervous system disease. The treatment of AN can be challenging, involving the judicious use of FM devices and hearing aids as well as cochlear implantation. A better understanding of the molecular basis of this disease will allow for more accurate diagnosis and a more individualized treatment approach.

Syndromic Recessive Disorders

Jervell and Lange-Nielsen Syndrome

Jervell and Lange-Nielsen (JLN) syndrome is a congenital disorder associated prolonged QT interval leading to episodes of arrhythmias and syncope that occur as early as the second or third year of life. These episodes are caused by a cardiac conduction defect and can lead to sudden death. Beta-adrenergic blockers (e.g., propranolol) and implantable cardioverter defibrillators have proved effective in managing the cardiac component of the syndrome.

The degree of hearing loss can vary, but it is almost always severe to profound. Clinicians should consider this diagnosis in children with hearing loss and unexplained syncope or in cases of a family history of syncope or sudden death. Patients suspected of having JLN syndrome should have an electrocardiogram; results will show large T waves and prolongation of the QT interval.

One form of JLN has been attributed to homozygosity for mutations of a potassium channel gene called *KVLQT1* (13) (Table 102.1). Other mutations in this gene cause the dominantly inherited long QT syndrome (Romano-Ward syndrome), which does not include hearing loss in the phenotype. Not all families with JLN syndrome map to this gene, clearly indicating genetic heterogeneity. Mutations also have been found in another potassium channel gene, *KCNE1* (14). In some families, heterozygous carriers of JLN syndrome show a prolonged QT interval but are otherwise asymptomatic.

Pendred Syndrome and Enlarged Vestibular Aqueduct Syndrome

First described in 1896, Pendred syndrome is a disorder in which hearing impairment is associated with abnormal iodine metabolism; the typical result is a euthyroid goiter. The gene that causes Pendred syndrome has been identified and is named *SLC26A4* (or *PDS*) (15) (Table 102.1). This gene produces a protein called pendrin, which is responsible for iodine and chloride ion transport. For known families with the full phenotype of Pendred syndrome (hearing loss and goiter), little evidence indicates genetic heterogeneity.

Hearing loss can be profound at birth or can progress with age. Radiologic studies demonstrate that most patients have severe cochlear dysplasia (Mondini deformity), enlarged vestibular aqueduct, or both. Although in the past the diagnosis of Pendred syndrome rested on a perchlorate discharge test indicating abnormal organification of nonorganic iodine, this test is not specific for Pendred syndrome and its sensitivity is not known. Thyroid function tests should also be obtained in these patients. Although the goiter is sometimes detected at birth, it usually does not become clinically evident until 8 years of age. Administration of exogenous thyroid hormone is the best therapy. Surgical extirpation of the thyroid gland has proved ineffective and is not recommended. Of cases of severe to profound congenital hearing loss, 1% to 2% are attributed to Pendred syndrome.

Enlarged vestibular aqueduct syndrome (EVAS) is similar to Pendred syndrome in that patients have hearing loss and inner ear dysplasia and either an isolated, enlarged vestibular aqueduct; incomplete partitioning of the cochlea; or both, but they lack thyroid pathology (Fig. 102.4) (16). Single *SLC26A4* mutations have been found in 15% to 20% of patients with EVAS. More recently, mutations have been identified in *FOXI1*, which compromise the transcription of *SLC26A4*, resulting in the phenotype found in EVAS (17).

Unlike patients with Pendred syndrome, those with EVAS have normal thyroid function. The degree of hearing loss can be variable, ranging from mild to profound, and the audiometric configuration is commonly either flat or downsloping. Hearing loss is either sensorineural or mixed, with a lower frequency conductive component and a mid- to high-frequency sensorineural component. Children with bilateral EVA and any *SLC26A4* mutation are more likely to have greater aqueduct enlargement and are more likely to experience more

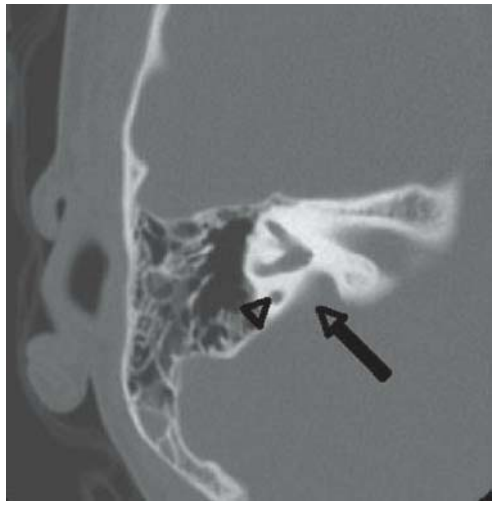

Figure 102.4 Enlarge vestibular aqueduct of the right ear. The vestibular aqueduct is grossly enlarged (*arrow*). The normal size should be less than 1.5 mm, about the size of the posterior canal (*arrowhead*).

significant progression of hearing loss (18). The cause of the conductive loss in patients with EVAS is unknown, and surgical correction of the ossicles is not recommended. Vestibular abnormalities occur in 5% to10% of cases, and they rarely occur without hearing loss. About 25% to 30% of patients with EVAS display hearing loss progression. There is an association between sudden hearing loss and head trauma in all patients with EVAS. Most patients, therefore, are counseled to avoid physical activities (e.g., contact football), which could cause such trauma. Molecular genetic testing for *SLC26A4* is available at select laboratories.

Usher Syndrome

Usher syndrome, characterized by hearing loss and retinitis pigmentosa, affects approximately one half of the 16,000 deaf and blind persons in the United States. The syndrome occurs in approximately 4.4 per 100,000 persons in the United States and in 3.0 cases per 100,000 persons in Scandinavia. Although Usher syndrome was initially recognized by Von Graefe (1858), it was named for Usher (1935), who emphasized its hereditary nature. Estimates of the prevalence of Usher syndrome among populations of deaf persons range from 0.6% to 28%, depending on the study population. Genetic linkage studies have shown this disorder to be genetically heterogeneous, with three clinically distinct subtypes that can be differentiated by the severity or progression of the hearing loss and the extent of vestibular system involvement (19). Patients with Usher syndrome type 1 (USH1) have congenital bilateral profound hearing loss and absent vestibular function. Those with Usher syndrome type 2 (USH2) have moderate hearing loss and normal vestibular function. Usher syndrome type 3 (USH3), which occurs primarily in Norwegians, involves progressive hearing loss and variable vestibular dysfunction. Although early studies estimated that USH1 accounted for nearly 90% of all cases of Usher syndrome and that USH2 represented only 10% or fewer cases, it is now recognized that these studies underestimated the prevalence of USH2 because patients with moderate hearing losses are not typically educated in schools for the deaf. Large series from both Scandinavia and the Unites States currently reflect a nearly equal number of cases of USH1 and USH2.

Genetic heterogeneity occurs both within and between these subtypes. Linkage analysis studies have revealed at least seven different causative genes for USH1 and at least three for USH2 (Table 102.1). In contrast, USH3 appears to have only one causative gene. To date, nine causative genes for Usher syndrome have been fully mapped. USH1 is most commonly caused by mutations in the myosin VII gene (*MYO7A*). All of the USH1 proteins have been found to be in a common molecular pathway in the hair cell stereocilia. This pathway appears to be involved with stereocilia or tip-link construction, maintenance, and function. The most common gene causing USH2 is *USH2A*, which produces a protein called usherin (20). The function of this protein is unknown, but it shares homology with laminin and fibronectin proteins and it is likely involved in extracellular matrix function.

An ophthalmologic evaluation is integral to the diagnosis of Usher syndrome. Results of electroretinographic studies have been reported to be subnormal in patients 2 to 3 years of age, before functional or fundoscopic abnormalities can be detected. Early diagnosis of Usher syndrome can have important implications on the rehabilitation of an affected child and on educational planning.

Autosomal Dominant Disorders

Identification of an autosomal dominant syndrome is facilitated by a family history that reflects a classic dominant inheritance pattern and a recognizable phenotype. In reality, variation in expressivity of dominant genes frequently leads to the presence of different phenotypic characteristics in various affected members of the same family. Decreased penetrance also is common with dominant genes, so an obligate carrier of the gene may not have any detectable phenotypic expression. When a new mutation occurs, an individual with no family history of the trait can actually have a disorder transmitted to offspring in a dominant manner.

As with recessive disease, advances in molecular genetics have greatly increased our understanding of the causes and mechanisms of autosomal dominant disorders. To date, 24 genes with an autosomal dominant nonsyndromic phenotype have been identified (21). Many of the common dominant syndromic phenotypes have been identified. This explosion of molecularly based knowledge brings the hope of a greater understanding of the intra- and interfamilial phenotypic variations seen in affected persons.

Nonsyndromic Dominant Disorders

Autosomal dominant nonsyndromic hearing loss (ADNSHL) is genetically heterogeneous. To date, 54 distinct loci have been identified through genetic linkage analysis of extended pedigrees. These loci are termed DFNA (DFN referring to deafness; A referring to dominant pattern of inheritance) followed by a number representing the order of discovery (e.g., DFNA1). The common clinical pattern of ADNSHL is that of postlingual progressive hearing loss, with onset in the second or third decade of life. Exceptions are DFNA2B, 10, 25, and 51, which, as with presbycusis, may not become clinically apparent until later in life. Additional exceptions are DFNA3, 6/14/38, 8/12, and 23, which cause prelingual deafness. The degree of progression and the audiometric frequency initially involved varies greatly with ADNSHL, depending on the genetic locus. Hearing loss progression in ADNSHL usually is incomplete, and most patients respond well to amplification. Some patients (i.e., DFNA1), however, do progress to complete hearing loss. As such, they are potential candidates for cochlear implantation.

Molecular genetic studies have elucidated the specific genetic abnormality in nearly half of the ADNSHL loci identified to date (Table 102.1). Examples of these genes include (a) membrane pores involved in signal transduction, such as the *KCNQ4* gene, which is a voltage-gated potassium channel at the DFNA2 locus; (b) connexins 26, 30, and 31, which are gap junction proteins at the DFNA3, DFNB1, and DFNA2 loci; (c) structural proteins, such as myosin VIIa, which causes DFNA11, DFNB2, and USH1B; (d) *COCH*, which causes DFNA9 and is a structural binding protein; (e) *TECTA*, a structural gene of the tectorial membrane, which causes DFNA12; (f) *COL11A2*, a collagen gene responsible for DFNA13; (g) developmental regulators, such as *POU4F3*, a transcription factor that causes DFNA15; (h) *HDIA1*, a gene with homology to the diaphanous gene in Drosophila, which causes DFNA1; and (i) several genes with unknown function (e.g., DFNA5).

Two genes with autosomal dominant inheritance have been linked to AN, *AUNA1*, and *PCDH9*. Starr et al. initially reported an extended large family with an auditory phenotype compatible with AN, segregating in a dominant fashion (22). Most affected patients had at least moderate SNHL, and many had a profound loss. These patients exhibited no other signs of neuropathies. Kim et al. subsequently identified the responsible gene as *AUNA1*, which is located on chromosome 13q14-21 (23). A recent study has identified two Italian families with AN but no mutations in the *AUNA1* gene. This group was found to have a mutation in protocadherin-9 (*PCDH9*), which is likely responsible for their AN (24).

Mutations in the *COCH* gene were found to be the cause of hearing loss in several large pedigrees (25). The hearing loss is present in the high frequencies during the second to fourth decades of life but progresses to profound in many patients by the fifth decade. Interestingly, many patients experience recurring bouts of vertigo similar to those seen in patients with Meniere disease. Usami et al. (26) found that *COCH* mutations were common in a significant proportion of Japanese patients with ADNSHL and vestibular symptoms, but *COCH* mutations were not identified in patients with classic Ménière disease. More recent work has identified a single region on chromosome 12p12 in three Swedish families, which may be responsible for Meniere disease in these patients (27).

Syndromic Dominant Disorders

Branchiootorenal Syndrome

Branchiootorenal (BOR) syndrome (also called Melnick-Fraser syndrome) is composed of conductive, sensorineural, or mixed hearing loss in association with abnormalities of branchial-derived structures (e.g., ear pits or tags, cervical fistulae) and renal anomalies that range from minor dysplasia, which usually is asymptomatic, to agenesis and renal failure. Cochlear dysplasia also is present in about 40% of patients, and its severity ranges from complete aplasia to a slightly smaller cochlea. BOR syndrome affects as many as 2% of children in schools for the deaf, thus emphasizing the importance of evaluating the renal status of any child with a hearing loss and an ear pit or branchial cleft anomaly (28) (Table 102.2).

TABLE 102.2 CLINICAL CRITERIA FOR BOR SYNDROME

Major Criteria	Minor Criteria
Branchial anomalies	*External ear anomalies*
Deafness	*Middle-ear anomalies*
Preauricular pits	*Inner ear anomalies*
Renal anomalies	*Preauricular tags*
	Other: facial asymmetry, palate abnormalities

The *EYA1* gene on chromosome 8q13 is the human homolog of the developmental Drosophila gene eyeless (Table 102.1). In 1997, Abdelhak et al. (29) first demonstrated that *EYA1* mutations were causal in BOR syndrome. *EYA1* encodes a transcript variant encoding 16 exons that span 159 kb of genomic DNA, translating into a protein of 559 amino acids. The putative function of the *EYA1* gene is that of a transcription factor involved in the morphogenesis of the ear, branchial structures, and kidney.

Based on historical data and loosely applied criteria for the diagnosis of BOR syndrome, only about 15% of affected persons had mutations in the *EYA1* gene. Based on more stringent contemporary criteria (Table 102.2), however, nearly 40% of patients have mutations in this gene. According to these criteria, BOR syndrome is defined as the presence of (a) three major criteria, (b) two major criteria and two minor criteria, or (c) one major criteria and an affected first-degree relative (30). Genetic testing for the *EYA1* gene is available in select laboratories.

Neurofibromatosis

Neurofibromatosis (NF) is a genetically heterogeneous disorder with two distinct forms, referred to as NF1 (classic neurofibromatosis) and NF2 (central neurofibromatosis). Both forms are associated with café au lait spots (light brown, variable-sized pigmented spots) and multiple fibromas; however, patients with NF2 have a lower prevalence of both of these cutaneous features. Both NF1 and NF2 have high penetrance but variable expressivity. Also, both have high mutation rates. NF1 is caused by a nerve growth factor gene (*neurofibromin*) on chromosome 17q11 (Table 102.1). NF2 is caused by the mutation of a tumor suppressor gene (*schwannomin*) on chromosome 22q12.

NF1 (also called von Recklinghausen disease) is diagnosed in approximately 1 of 3,000 persons per year. It is associated with a large number of café au lait spots and cutaneous neurofibromas, as well as plexiform neuromas, pseudoarthrosis

(particularly of the tibia), Lisch nodules of the iris, and optic gliomas. Although cutaneous tumors are the most common feature, also seen is involvement of the central nervous system, peripheral nerves, and viscera. The phenotype can be limited to a few café au lait spots or be expressed as multiple disfiguring tumors. Central nervous system lesions can produce mental retardation, blindness, or hearing loss, but these complications are uncommon. Although hearing impairment can be caused by a neurofibroma encroaching on the middle or inner ear, marked deafness is rare. True acoustic neuroma, which typically is unilateral, occurs in only 5% of patients. Children with this disorder require mandatory longitudinal audiologic follow-up evaluations.

NF2 is characterized by bilateral acoustic neuromas (vestibular schwannomas). These lesions usually grow slowly and are asymptomatic until young adulthood, when tinnitus and vestibular dysfunction often present. NF2 is associated with a higher risk of tumors of the central nervous system and spinal cord, but Lisch nodules and optic glioma are not present in affected patients. Genetic testing of the NF2 gene, which is available for presymptomatic family members who are at risk, facilitates early diagnosis and treatment.

Stickler Syndrome

Stickler syndrome is a relatively common genetic disorder characterized by typical facial characteristics (e.g., Robin sequence), hypermobility and enlargement of joints associated with the onset of arthritis in early adulthood, myopia severe enough to involve retinal detachment or cataracts, and occasionally spondyloepiphyseal dysplasia. Some degree of hearing loss occurs in as many as 80% of patients, and substantial sensorineural or mixed hearing loss, often progressive, is present in approximately 15%. The variation in expressivity that occurs with Stickler syndrome can be attributed to both allelic and genetic heterogeneity, which complicates diagnosis of the disorder.

Multiple types of Stickler syndrome are seen, each attributed to mutations in a different gene:

- Stickler syndrome type 1 (STL1) is the classic phenotype. It is associated with mutations in the *COL2A1* gene, a fibrillar collagen that is arrayed in quarterstaggered fashion to form fibers (Table 102.1). The STL1 phenotype includes cleft palate deformity, progressive myopia, vitreoretinal degeneration, premature joint degeneration with abnormal epiphyseal development, midface hypoplasia, irregularities of the vertebral bodies, and variable degrees of hearing loss. Different mutations of the same gene produce similar but more severe conditions, namely, Kniest syndrome and spondyloepiphyseal dysplasia congenita, both of which also include progressive SNHL (31).
- Stickler syndrome type 2 (STL2) is caused by mutations in the *COL11A1* gene. Persons with STL2 have the characteristic ocular, auditory, and orofacial features of STL1.
- STL3 is caused by mutations in the *COL11A2* gene, which result in a disease characterized by the typical facial features associated with STL1 together with hearing impairment. Cleft palate and mild arthropathy can also occur; however, ocular abnormalities (e.g., high myopia, vitreoretinal degeneration, and retinal detachment) are absent. The phenotypic differences between STL1 and 2 and STL3 can be explained by the absence of *COL11A2* in the vitreous (31).
- A fourth gene, *COL9A1*, can cause Stickler syndrome that is inherited in an autosomal recessive fashion (32).

Treacher Collins Syndrome

Treacher Collins syndrome (mandibulofacial dysostosis) is a craniofacial disorder with manifestations that include microtia, aural meatal atresia, and conductive hearing loss caused by ossicular chain malformations; the latter occurs in approximately 30% of patients. SNHL and vestibular dysfunction also can be present.

The hearing loss varies, depending on the degree of severity of the malformation of the ear, and ranges from mild to severe. As such, hearing reconstructive procedures are technically challenging. The usual facial findings are malar hypoplasia, including underdeveloped zygomatic arches with resultant downward slanting palpebral fissures, coloboma of the lower eyelids, and a hypoplastic mandible. Symmetric facies and bilateral eyelid coloboma differentiate this syndrome from Goldenhar spectrum and other oculoauricular vertebral syndromes that include similar but unilateral microtia and craniofacial abnormalities.

Penetrance is high and the oculoauriculovertebral spectrum is sporadic and thought to be multifactorial. The syndrome is often caused by an abnormality in the *TCOF1* gene, which functions in early craniofacial development. In as many as 60% of affected individuals, however, the disorder is caused by new mutations. The resulting protein has been named treacle (Table 102.1). Although no evidence indicates genetic heterogeneity, considerable inter- and intrafamilial variability are seen, indicating that other genes can modify the expression of the treacle protein (33).

Waardenburg Syndrome

Waardenburg syndrome (WS) exemplifies a syndrome with variable expressivity. This syndrome is characterized by varying degrees of unilateral or bilateral SNHL and various pigmentary anomalies (e.g., white forelock, heterochromia iridis, premature graying, and vitiligo) and variable craniofacial features (e.g., dystopia canthorum, broad nasal root, and synophrys). The white forelock is present in only 20% to 30% of cases, with a variable age of first appearance. Recent data have shown that enlarged vestibular aqueducts also are present in as many as 50% of patients (34).

There are four types of WS, with the most common being type 1 (WS1) and type 2 (WS2). These clinical types are distinguished on the basis of the presence of dystopia canthorum (WS1) or its absence (WS2). Hearing loss occurs

in approximately 20% of individuals with WS1 and more than 50% of those with WS2. Lateral displacement of the medial canthi may not be immediately apparent, and indices based on objective measures of the distances between anatomic landmarks (e.g., the inner canthi, pupils, and outer canthi) are helpful in making a determination. If only one or a few characteristics are present in each family member, definitive diagnosis of WS can be difficult. WS3 (Klein-Waardenburg syndrome) includes the features of WS1 and skeletal malformations, particularly of the hands and forearms. WS4 (Waardenburg-Shah syndrome) differs from the other three types in that it is a heterogeneous disorder with either autosomal recessive or autosomal dominant inheritance. Phenotypic features are similar to those of WS2; however, it occurs in association with Hirschsprung disease. The importance of obtaining a complete history of the extended family in questionable cases cannot be overemphasized. Audiologic screening of family members can help identify previously unsuspected unilateral hearing loss.

Six different genes for WS have been identified and located: *PAX3*, *MITF*, *SNAI2*, *EDNRB*, *EDN3*, and *SOX10*. Mutations in the *PAX3* gene cause WS1 and WS3 (35). This gene is located on chromosome 2q37 (Table 102.1) and controls some aspects of the development of the face and inner ear. Mutation of the mouse homolog of this gene produces a condition called splotch, which includes pigmentary and ocular abnormalities in the heterozygote (36). Only the homozygote has hearing loss, however, and has far more severe neural tube defects. Approximately 20% of cases of WS2 are attributable to a mutation of the microphthalmia-associated transcription factor (*MITF*) gene on chromosome 3p12-14. Again, a mouse homolog with mutation of the same gene is known, but these animals are not deaf in the heterozygous state. Recently, a second WS2 gene called *SNAI2* was identified on chromosome 8q11. Experimental evidence has shown that *MITF* activates the promoter of *SNAI2*, thereby linking these genes in the neural crest developmental pathway. WS4 can be caused by mutations in the endothelin-B receptor gene (*EDNRB*), endothelin 3 (*EDN3*), or *SOX-10*.

X-Linked Disorders

Sex-linked disorders are caused by genes on the X or Y chromosome. Because no known hearing loss genes are found on the Y chromosome, the disorders discussed in this chapter are all X-linked. This pattern of inheritance is uncommon in hearing disorders, accounting for only 1% to 2% of cases. It is, however, associated with up to 5% of nonsyndromic profound hearing loss in males.

Nonsyndromic X-Linked Disorders

Five loci on the X chromosome for nonsyndromic hearing loss are known. The most well-characterized phenotype is related to X-linked stapes fixation with perilymphatic gusher. This has been localized to the DFN3 locus, which encodes the *POU3F4* transcription factor, and is associated with progressive mixed hearing impairment. Females can have mild expression of this gene. The *POU3F4* gene is located close to a gene that causes choroideremia, which is a condition characterized by progressive vision loss secondary to atrophy of cells within the retina and choroid. Deletion of these genes produces the contiguous gene syndrome of choroideremia, hearing loss, and mental retardation. Preoperative temporal bone CT scanning can be used to detect predictive findings, such as an enlarged internal auditory canal with thinning or absence of bone at the base of the cochlea. Because of the high risk of a gusher, stapes surgery should be considered cautiously for any young male patient, particularly one with an X-linked family history or with choroideremia.

Syndromic X-Linked Disorders

Norrie Disease

Norrie disease is a rare congenital neurodevelopmental disorder characterized by rapidly progressive blindness with bilateral pseudoglioma and exudative vitreoretinopathy, opacification, and ocular degeneration that results in microphthalmia. Progressive SNHL, with onset in the second or third decade, affects approximately one-third of patients. In some families, progressive mental deterioration also occurs. The gene responsible for Norrie disease, *NDP*, produces a protein called norrin and appears to be a growth factor similar to transforming growth factor β, which is responsible for vasculogenesis. Some families have variable deletions in this chromosomal region, and deletions involving contiguous genes, particularly the monoamine oxidase genes, may account for the variable finding of mental deficiency. On the other hand, mutations entirely within the *NDP* gene also have produced progressive mental retardation (37).

Otopalatodigital Syndrome

Otopalatodigital syndrome consists of hypertelorism, craniofacial deformity involving the supraorbital area, flat midface, small nose, and cleft palate. Affected persons are short, have broad fingers and toes that vary in length, and have an extremely wide space between the first and second toes. Conductive hearing loss usually is caused by an ossicular malformation, which may be amenable to surgical intervention. Female carriers can have mild manifestations of the disorder. The gene has been mapped to Xq28 (38).

Wildervanck Syndrome

Wildervanck syndrome comprises the Klippel-Feil malformation involving fused cervical vertebrae, sensorineural or mixed hearing loss related to bony malformation of the inner ear, and paralysis of the sixth cranial nerve, which causes retraction of the eye on lateral gaze (Duane retraction syndrome). Hearing loss in Wildervanck syndrome almost always occurs in females, raising the possibility of X-linked

dominant inheritance or polygenic inheritance with lethality in males. Isolated Klippel-Feil sequence includes hearing loss in approximately one-third of cases, but it is rarely familial. Hearing loss also can be associated with Duane retraction syndrome in a small percentage (less than 10%) of cases (39).

Alport Syndrome

Alport syndrome is characterized by varying degrees of progressive SNHL and with progressive glomerulonephritis that leads to end-stage renal disease. Hearing loss may not become manifest until the second decade of life. Renal disease, which can manifest as hematuria in infancy ("red diaper"), usually remains asymptomatic for several years before its onset. This component is especially severe in males, often causing death from uremia before 30 years of age. Early diagnosis of this syndrome is essential to facilitate management of the renal disease. Alport syndrome is genetically heterogeneous, with X-linked inheritance accounting for 85% of cases, caused by mutation of a type 4 collagen gene (*COL4A5*) (40). Mutations of *COL4A3* and *COL4A4* produce an autosomal recessive form of Alport syndrome, but expression still is more severe in males. Fechtner syndrome is a similar autosomal dominant disorder, which is associated with progressive hearing loss, renal disease, and macrothrombocytopenia.

Deafness Dystonia Optic Atrophy Syndrome

Deafness dystonia optic atrophy syndrome (Mohr-Tranebjaerg syndrome) is a rare neurodegenerative syndrome characterized by progressive SNHL, vision loss, dystonia, fractures, and mental deterioration. It is caused by a mutation of *TIMM8A* (initially named *DDP*, Deafness Dystonia Peptide), which is involved in the translocation of proteins across the inner mitochondrial membrane into the mitochondrial matrix (41,42).

MITOCHONDRIAL DISORDERS

Mitochondria are cytoplasmic organelles that contain small pieces of nonnuclear DNA in a ring form. Each mitochondrion contains two to ten copies of the mitochondrial genome. Each copy is composed of approximately 16 kb, which contain the genes for messenger, ribosomal, and transfer RNA needed for the synthesis of mitochondrial proteins. These proteins interact with proteins encoded by the nuclear chromosomes to facilitate energy production through synthesis of adenosine triphosphate and oxidative phosphorylation. Mutations in the mitochondrial genome can affect this energy production. As a result, tissues that require high levels of energy (e.g., muscle) are disproportionately affected. The mutation rate of mitochondrial DNA exceeds that of nuclear DNA because the DNA repair mechanisms in the mitochondria are less effective.

Mitochondrial inheritance is distinctly different from the inheritance pattern of nuclear genes. Because sperm transmit few or no mitochondria, nearly the entire contribution is from the egg. The result is matrilineal inheritance that affects male and female offspring equally. If a mother is homoplasmic for a mitochondrial mutation, all of the offspring are affected. Among hundreds of mitochondria in each cell, only a small fraction can contain a specific mutation, a condition known as heteroplasmy, and different percentages of mutated mitochondria can be present in different tissues.

Mitochondrial Nonsyndromic Hearing Loss

Recently, progress has been made in understanding the association of mitochondrial mutations with nonsyndromic hearing loss and ototoxicity. Several mutations in the 12S rRNA and the $tRNA^{ser}$ genes have been genetically and biochemically linked to hearing loss. Of particular clinical relevance, patients with 12S rRNA mutations have been found to have a genetic predisposition to aminoglycoside-induced hearing loss. Milder hearing loss can be expressed among family members with these mutations who have not been exposed to aminoglycosides (Fig. 102.5). The 961, 1,494, and 1,555 loci are linked to the genetic predisposition to aminoglycoside-induced hearing loss. The A1555G mutation is the one most reported, but a variety of mutations at the 961 loci may prove to be more prevalent. It is estimated that 1,555 mutations are present in about 2% of the hearing loss population and about 0.5% of the general population in the United States. Mitochondrial mutations that predispose patients to aminoglycoside ototoxicity may be present in 1% to 2% of newborns. The relatively high prevalence of these mutations would render 12S rRNA genetic screening valuable to neonatologists. The mechanism of this ototoxic effect may be related to these mutations, making the12S rRNA structurally similar to the 16S rRNA found in bacteria. The bacteriocidal effect of aminoglycosides has been found to occur in the16S rRNA (43).

Because gradual accumulation of mitochondrial mutations in affected tissues can worsen the phenotype over time, some authors have postulated a mitochondrial role in presbycusis. As yet, however, no definitive evidence exists. Additionally, a few families reportedly have nonsyndromic hearing loss because of the combination of a mitochondrial mutation and a recessive mutation in the nuclear gene.

Mitochondrial Syndromic Disorders

Mitochondrial diseases typically involve progressive neuromuscular degeneration with ataxia, ophthalmoplegia, and progressive hearing loss. Syndromes involving SNHL include the following:

- Mitochondrial encephalopathy, lactic acidosis, and stroke (MELAS). Hearing loss occurs in approximately 30% of patients. Findings are highly variable and can include intermittent vomiting, limb weakness, and stroke-like episodes, which can result in hemiparesis and cortical blindness. It is often associated with short stature.

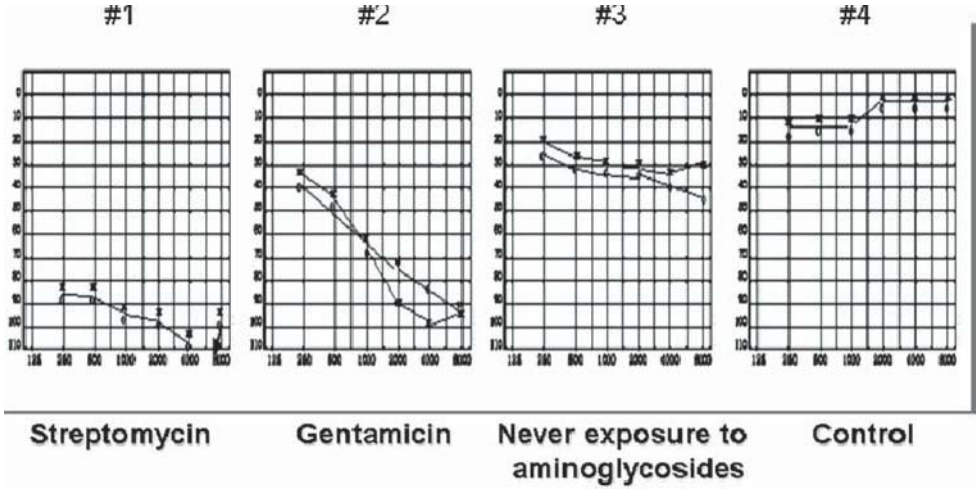

Figure 102.5 Representative audiograms of a family with #1 to 3 having a mutation in the 12SrRNA gene while #4 in unaffected. #1 and #2 received aminoglycoside antibiotics and develop significant hearing loss. Patient #3 only had a mild hearing loss phenotype from the mutation.

- Maternally inherited diabetes and deafness (MIDD). This condition has been attributed to a unique mitochondrial mutation in the same $tRNA^{lys}$ gene that causes MELAS. Additionally, cases of MIDD have been linked to large deletions, insertions, and point mutations in the $tRNA^{glu}$ gene (44).
- Kearns-Sayre syndrome. In addition to SNHL, findings include ataxia, heart block, progressive ophthalmoplegia, and retinopathy.
- Myoclonic epilepsy with ragged red fibers. In addition to variable degrees of SNHL, findings include ataxia, epilepsy, myoclonus with dementia, and optic atrophy occurring in some cases.

CHROMOSOMAL SYNDROMES

Down Syndrome

Middle-ear and mastoid disease are often seen in children with Down syndrome (Trisomy 21), but SNHL may also be present. Careful audiologic and tympanometric follow-up evaluation are essential. Trisomy 13 is often lethal in the newborn period, but survivors can have marked SNHL.

Turner Syndrome

Turner syndrome, monosomic for all or part of one X chromosome, generally presents in females as gonadal dysgenesis, short stature, and often a webbed neck or shield chest. Sensorineural, conductive, or mixed hearing loss can be present. Hearing loss can be progressive and can constitute the first evidence of the syndrome in prepubescent girls.

MULTIFACTORIAL GENETIC DISORDERS

Some genetic disorders cannot be attributed to the action of a single gene but are caused by the interaction of genetic factors and environmental influences. Clefting syndromes that are associated with conductive hearing loss and the Goldenhar spectrum are both examples of this type of inheritance. In the latter, a positive family history can be found in approximately 6% of cases, but different aspects of the spectrum can occur even within the same family. Findings include preauricular tags or pits, vertebral anomalies (e.g., hypoplastic vertebrae or hemivertebrae in the cervical region), epibulbar dermoids, and coloboma of the upper lid. The Goldenhar spectrum (also called oculoauriculovertebral dysplasia) has been described in some families as being inherited in an autosomal dominant pattern but clustering in a single family. Other conditions thought to represent multifactorial inheritance are the increased susceptibility to hearing loss that is associated with diabetes and hyperlipidemia.

Otosclerosis

Clinical otosclerosis has a reported prevalence of 0.2% to 1% among white adults, making it the single most common cause of hearing impairment in this population. The mean age of onset is in the third decade of life, and 90% of affected persons are younger than 50 years of age at the time of diagnosis. A preponderance of women are affected, suggesting a possible hormonal influence. This disorder is characterized by isolated sclerosis of the endochondral bone of the inner ear. Conductive hearing loss develops when otosclerotic foci invade the stapediovestibular joint (oval window) and interfere with the free motion of the stapes. SNHL also may be present. Histopathologic examination shows measles virus particles within the bony overgrowth, indicating the possibility of an interaction with the viral genome.

Although in most patients the cause of otosclerosis is unknown, studies of large families with this disorder indicate an autosomal dominant inheritance pattern with incomplete penetrance. Penetrance rates ranging from 25% to 40% have been estimated. Genetic heterogeneity is likely, and some genes are more penetrant than others. Although no specific genes have been identified, seven loci have been mapped in these families.

HEARING LOSS EVALUATION AND GENETIC COUNSELING

Great strides have been made in identifying hearing-impaired infants. Early detection and hearing intervention (EDHI) programs are currently ongoing in a large number of centers throughout the United States. These programs are based on what is referred to as the "one-three-six rule" (45). Hearing screening is carried out before 1 month of age, definitive audiometric evaluation is performed before 3 months of age, and enrollment in rehabilitation programs is accomplished by 6 months of age. To date, 42 states have legislated EDHI programs. In the remaining states, many medical centers have initiated voluntary newborn screening programs.

When faced with pediatric patients with an identified hearing loss, clinicians must carefully review the prenatal, perinatal, and postnatal medical history. They should assemble a detailed family history, including a pedigree chart that includes third-degree relatives. Queries should be directed toward determining the health and hearing status of other family members who may have subtle manifestations (e.g., ear pits) that could represent variable phenotypic expressing of a hearing loss syndrome. Previous audiologic data from the patient and other family members should also be reviewed to validate the history and determine whether familial progressive hearing loss is involved. Also, a thorough physical examination should be performed to detect subtle signs of a possible genetic syndrome. Depending on the history and physical findings, other clinical consultations (e.g., genetics, ophthalmology), radiographic imaging, and laboratory studies may be needed.

In the past, a simultaneously conducted, comprehensive diagnostic evaluation was advocated for pediatric patients with SNHL. Recently, however, data have shown that a stepwise evaluation is a far more prudent and cost-effective paradigm (46). Children with bilateral severe-to-profound SNHL should undergo genetic screening as the initial step, whereas children with milder types of SNHL or unilateral SNHL should undergo imaging first (46). Additional genetic testing for mitochondrial mutations, *GJB6* and *SLC26A4*, are also available for select patients.

Genetic counseling provides parents with information regarding the cause of their child's hearing loss and the expected pattern of inheritance of a genetic disorder. Counselors, as well as other members of the otologic team, must realize that a number of unique clinical and genetic situations can arise. First, they may encounter couples who are deaf. These couples may not view having a deaf child as a burden. Rather, they may be proud of their heritage, their language (American Sign Language), and the accomplishments of deaf persons throughout history. Sensitivity to this perspective is essential, as is the availability of an interpreter who can communicate genetic terminology (47). Even in marriages in which both persons are deaf, unless the partners have an identical genetic cause of the hearing loss, the actual risk of having an affected child is slight. Second, all professionals should be aware that mitochondrial disorders have a unique inheritance pattern that is often missed. The risk of a mitochondrial disorder depends on whether the mother is homoplasmic or heteroplasmic and whether other genetic or nongenetic factors are necessary for expression. Offspring of a man with a mitochondrial disorder are not at risk. Lastly, a problem commonly encountered with nonsyndromic hearing loss is the presence of phenocopies, which are two distinct causes having the same phenotype. For example, a clinician may be faced with a patient who has an infection-related or environment-related hearing loss. This patient may belong to a family with a history of genetic hearing loss. These phenocopies would make gene identification studies and the clinical prediction of recurrence risk very difficult.

In sum, rapid advances in molecular genetics have had a direct impact on clinical practice, and it is essential that clinicians responsible for the management of pediatric patients with heritable hearing loss become familiar with these advances. The future holds the promise of effective strategies to accurately screen for, diagnose, prevent, and ameliorate these losses.

HIGHLIGHTS

- Several population studies have estimated that 50% of cases of childhood hearing loss are caused by genetic factors. Of these, 75% to 80% involve autosomal recessive genes; the remainder are dominant, X-linked, mitochondrial, and chromosomal.
- Genetic hearing loss can be congenital or delayed in onset, progressive or nonprogressive, unilateral or bilateral, and syndromic or nonsyndromic. Genetic hearing loss syndromes are commonly classified according to the other systems involved. Nonsyndromic hearing disorders are classified according to audiologic characteristics, age at onset, presence or absence of progression, and mode of inheritance.
- Human genes are arranged linearly on 23 pairs of chromosomes, composed of 22 pairs of autosomes and 1 pair of sex chromosomes. A gene can have several alternative codes or alleles. The genotype for a specific trait can consist of two identical alleles (hemizygous) or two different alleles (heterozygous).
- Phenotype is determined by which alleles are present and how they interact. A dominant allele is expressed in the homozygous or heterozygous state, whereas an autosomal recessive allele is expressed only in homozygotes. Recessive X-linked genes are expressed in males but usually not in female carriers. Certain dominant genes have variable

penetrance and expressivity, even within the same family. Heritable disorders also can be caused by abnormalities at the chromosomal level.

- Autosomal dominant disorders associated with hearing loss include WS, Stickler syndrome, BOR syndrome, Treacher Collins syndrome, NF, otosclerosis, and at least four forms of nonsyndromic hearing loss.
- Autosomal recessive disorders associated with hearing loss include Usher syndrome, Pendred syndrome, JLN syndrome, and at least three subtypes of nonsyndromic hearing loss. Mutations of the *GJB2* gene account for the cause of hearing loss in up to 50% of all patients presenting with autosomal recessive SNHL.
- Major X-linked disorders that include hearing loss are Norrie disease, otopalatodigital syndrome, Wildervanck syndrome, Alport syndrome, and several types of nonsyndromic congenital severe SNHL. Examples of multifactorial inheritance are clefting syndromes and the Goldenhar spectrum.
- Mitochondrial-related hearing loss accounts for about 2% of cases of SNHL. Some cases have multisystem involvement, but most are thought to be nonsyndromic. Of particular clinical relevance, specific mutations in the 12S rRNA gene are related to aminoglycoside ototoxicity.
- Counseling about genetic hearing loss is complex because family histories often involve a number of marriages between deaf persons with hearing losses of uncertain causation. A sequential evaluation paradigm is warranted, with genetic testing being the cornerstone of the evaluation.

103 Comprehensive Cleft Care

Alexander J. Davit III *Todd Otteson* *Joseph E. Losee*

Despite the numerous advances in caring for patients affected with cleft lip and/or palate (CL/P), parents who learn their child is affected can often feel considerable anxiety and confusion over the significance of this diagnosis. In order to better care for cleft patients and their families, treatment protocols have evolved that utilize a multidisciplinary team-based approach, incorporating skills offered by several subspecialties, including otolaryngology, plastic surgery, orthodontics, pediatric dentistry, speech pathology, audiology, psychology, and social services. Each discipline is focused on delivering coordinated, comprehensive care to the cleft patient.

Numerous authors have written extensively on this challenging subject; this chapter is intended to serve as a detailed outline for the evaluation and treatment of patients affected with CL/P, focusing on the salient points of comprehensive cleft care. At the Children's Hospital of Pittsburgh of UPMC, our cleft team focuses on every stage in each patient's development where intervention may be considered to benefit the patient. It is important to recognize that caring for the child with a cleft is a long-term process, extending from infancy into early adulthood, and is a journey with several important "stops" along the way. During the child's first year of life, the primary focus of care is in promoting proper nutrition and growth, while also performing the initial soft tissue reconstructions. Repairing the CL/P in a skilled manner is of utmost importance, thereby laying the foundation for the patient's future facial appearance, but it is hardly the final procedure for most patients today. After infancy, a major focus is on speech outcomes, when selected patients may benefit from revisional speech surgery to address velopharyngeal insufficiency. During the period of mixed dentition, the patient is evaluated for alveolar bone grafting and "touch up" revisional soft tissue procedures to the lip and nose. In late adolescence, patients are considered for orthognathic surgery and definitive rhinoplasty to refine the patient's "final result." During this entire process, the cleft team routinely follows patients in order to assess their individual needs with regard to appearance, psychosocial development, speech, hearing, orthodonture, and dentistry. Comprehensive team care of the cleft patient can be a clinically gratifying endeavor, one that necessitates a multidisciplinary approach to deliver reproducible, high-quality results for the patient.

EPIDEMIOLOGY: INCIDENCE AND GENETIC FACTORS

CL/P is one of the most common congenital anomalies: the prevalence in North America is currently 0.2 to 2.3 cases per 1,000 population, while the prevalence of isolated cleft palate (CPO) is 0.1 to 1.1 cases per 1,000 (1,2). For CL/P, these rates vary between ethnic subgroups: 3.6 per 1,000 in Native Americans, 2.1 per 1,000 in Asians, 1 in 1,000 in Caucasians, and 0.41 per 1,000 in African Americans (1,3,4). CPO has a relatively stable incidence across ethnic subgroups (1). The male to female ratio for CL/P is 1.5 to 2.0:1 (2). For CPO, the converse is true; females are more commonly affected, with a male to female ratio of 1:2 (2).

Development of CL/P or CPO is believed to be a complex, multifactorial process involving multiple risk factors, genetic mutations, family history of orofacial clefting (OFC), maternal diseases and behaviors, fetal exposure to teratogenic medications, and nutritional deficiencies or excesses. A positive family history of OFC has long been recognized as a strong risk factor and was first studied in 1942, when Fogh-Anderson began to apply statistical analysis to familial inheritance patterns of CL/P (1). Genetic studies in both humans and mice have identified transforming growth factor beta 3 (TGFβ3) and msh homeobox 1 (MSX1) as genes that play an important part in the development of CL/P (1).

While most cases of CL/P and CPO are nonsyndromic, there are a multitude of genetic syndromes that may be associated with CL/P and CPO. The most common syndrome associated with CL/P is Van der Woude syndrome, an autosomal dominant syndrome characterized by blind lower lip pits in addition to CL/P (5). The most common syndromic diagnoses associated with CPO are the autosomal dominant syndromes caused by microdeletions or additions of chromosome 22q11.2: DiGeorge syndrome, conotruncal anomaly face syndrome, and velocardiofacial syndrome; these have an incidence rate of 1:4,000 live births (5,6). Other syndromes associated with CPO include Stickler syndrome, popliteal pterygium syndrome, and ectrodactyly ectodermal cleft syndrome (5).

Environmental factors are also believed to play a pivotal role in the development of CL/P. These factors can be grouped into several categories: maternal health, teratogenic substances, and nutritional factors. The association between birth defects and maternal illnesses such as diabetes mellitus and gestational diabetes has been studied extensively; an increased incidence of congenital malformations is notably higher in patients with diabetes mellitus, but not gestational diabetes (2). Maternal obesity has also been studied as a risk factor for CL/P and CPO, and women with a BMI greater than 29 kg/m^2 have been shown to have a 1.3 times higher risk of having a child with a cleft when compared to women with nonobese BMI values (2). Teratogenic medications associated with development of CL/P include valproic acid, phenytoin, retinoic acid, dioxin, and thalidomide (1). Maternal tobacco smoking has been implicated in the development of OFC: CL/P and CPO are approximately 1.2 times more likely than in the general population (2). Although the children of women who consume heavy amounts of alcohol during pregnancy are known to be at increased risk for congenital malformations, the specific relationship between the development of OFC and maternal alcohol consumption remains unknown (2). Based on previous animal studies, maternal folic acid supplementation has frequently been considered to have a protective effect with regard to CL/P, although in a case–control study in the United Kingdom, higher maternal folic acid intakes were not associated with a lower incidence of OFC (7).

EMBRYOLOGY

Embryologic formation of the nose and upper lip begins during the fourth week of gestation, when the bilaminar prechordal plate containing ectodermal and endodermal elements is formed. This structure gives rise to the stomodeum, or primitive mouth, about which five facial prominences develop: the frontonasal prominence, paired maxillary prominences, and paired mandibular prominences (8).

Development of the upper lip and nose is controlled by several developmental pathways, including sonic hedgehog (SHH), wingless type (Wnt), bone morphogenic protein (BMP), and fibroblast growth factor (FGF) (9). Fusion of the frontonasal and maxillary processes begins to evolve in the anterior face at approximately 32 days' gestation, when the ventrolateral aspects of the frontonasal prominence undergo cellular proliferation to form the nasal placodes, which in turn give rise to the medial and lateral nasal processes (9). During this process, the maxillary processes also undergo rapid mesenchymal growth, and at the 38th day of gestation, fusion commences between these processes and the lateral and medial nasal prominences, approximating the distal tips of the medial and lateral nasal processes, eventually causing contact and fusion between them (9,10) (Fig. 103.1). Further development of the upper lip and nose follows, with the continued growth of the maxillary processes causing anteromedial positioning of the nasal pits, which undergo further maturation into the nasal ducts (9). Upper lip development is typically complete by the 48th day of gestation, once the interposed epithelial elements have undergone apoptosis and the remaining mesenchymal elements undergo final fusion between the maxillary and medial nasal prominences, to be followed by anteroposterior formation of the primary and secondary palate (9).

Palatal anatomy is subdivided into the primary and secondary palates, with the primary palate being formed by the frontonasal prominence and the secondary palate being formed by the paired lateral maxillary prominences (8). In the eighth week of normal embryologic development, the tongue begins to be withdrawn from its position between the lateral maxillary prominences, and they begin to shift from a vertical to horizontal orientation, ultimately undergoing fusion in the normal fetus (8). Several different mechanisms are believed to contribute to this vertical migration, including increased mesenchymal proliferation, increased tissue fluid content, and multiple signaling pathways, including platelet-derived growth factor, FGF10, SHH, and TGFβ3 (8). Once the palatal shelves meet in the midline, the line of fusion forms in the midpoint of the hard palate, later progressing both anteriorly and posteriorly from this point (8).

PRENATAL DIAGNOSIS AND COUNSELING

Prenatal diagnosis of CL/P, along with other developmental anomalies, has become more common with the widespread use of screening ultrasonography. It is important to recognize that approximately 50% of children with cleft lip and alveolus have other anomalies as well; 22% have an abnormal karyotype (11). In several large studies, it was possible to identify an isolated cleft lip deformity by ultrasound approximately 30% to 55% of the time at 24 weeks' gestation (11,12). The high variability in detection rates is believed to be due to differences in each center's ultrasonographic examination protocols (12). The ability to identify CPO on ultrasound is significantly lower,

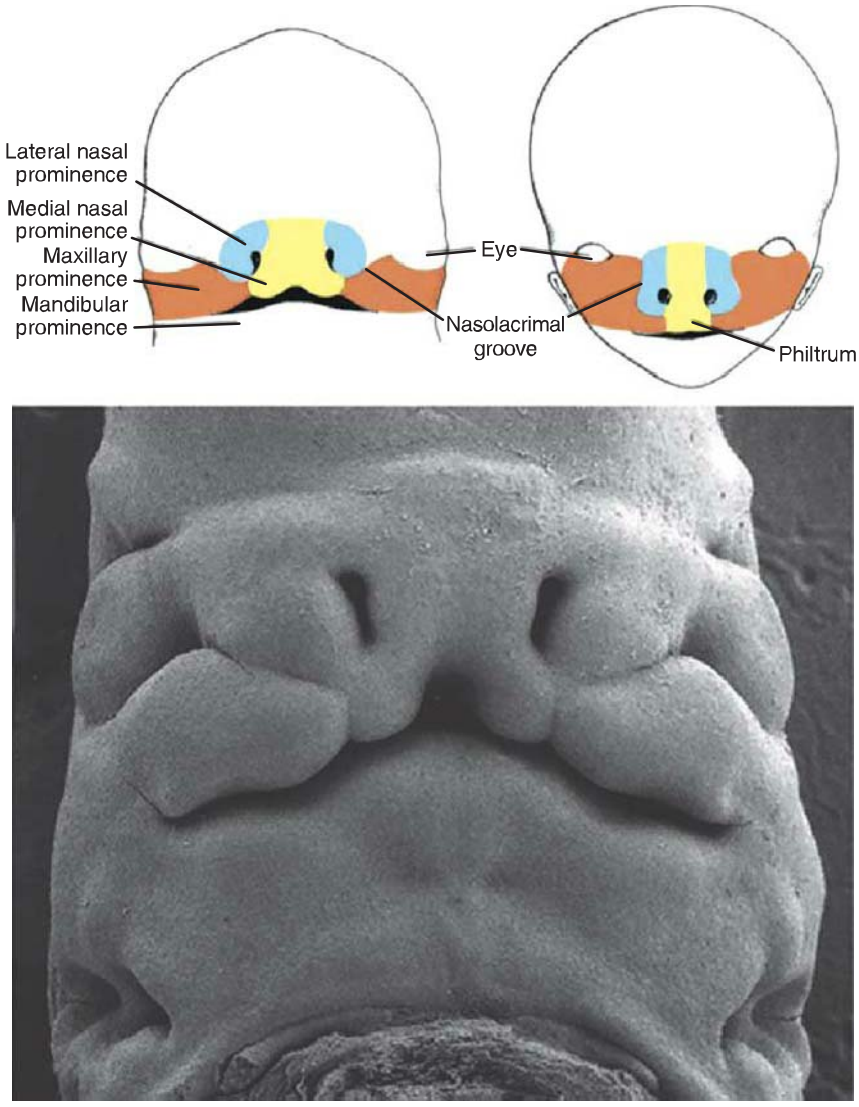

Figure 103.1 Facial development in the embryo. Note the development of the upper lip, philtrum, and nose from the maxillary, medial nasal, and lateral nasal prominences. (From van Aalst J, Kolappa KK, Sadove M. Nonsyndromic cleft palate. *Plast Reconstr Surg* 2008;121(1):1–14, with permission.)

with a rate of 1.4% in the Eurofetus study (11). Detection rates with newer imaging modalities, such as 3-D ultrasound and MRI, have yet to be fully elucidated at this time.

The goal of detecting OFC in the prenatal period is to allow parents to obtain appropriate genetic counseling, emotional support, and treatment planning. In counseling parents with regard to CL/P, it is important to discuss the potential recurrence risk, so informed choices with future family planning may be made. Population studies have determined the statistical risk of having a second child with CL/P or CPO. In first-degree relatives of patients with a nonsyndromic OFC, the risk of having a child with CL/P is approximately 3% to 4% (13). For patients affected with CPO, the risk for first-degree relatives is approximately 1.8% (13). For an affected parent with CL/P who already has one affected child, the recurrence risk is approximately 10% to 17% (5,8). For an affected parent with CPO who already has one affected child, the risk is slightly lower, 8% to 15% (13) (Table 103.1).

TABLE 103.1 FAMILIAL RISKS FOR NONSYNDROMIC CLEFT LIP AND PALATE

Family History	Cleft Lip ± Cleft Palate	Cleft Palate
No family history of cleft lip or cleft palate	0.1%	0.04%
Unaffected patients with		
One previously affected child	4%	2%
Two previously affected children	9%	1%
One affected parent	4%	6%
One affected parent and one previously affected child	17%	15%

± = with or without

FEEDING THE CLEFT PATIENT

Establishing a reliable oral feeding strategy is critical for patients born with OFC. Patients with wide, complete clefts often have significant initial challenges with oral feeding, since the cleft prevents them from making an adequate seal on the bottle or breast (14). This can lead to inefficient suckling, resulting in the infant tiring more readily. Because of the ineffectual seal, patients often swallow a significant amount of air during feeds and require more aggressive burping during and after feeding. Most cleft patients will be able to feed well orally with the assistance of bottles with softer nipples and/or a valve flow control system. In addition, modified positioning that places the infant's head in a more vertical position helps to avoid significant reflux and air swallowing in many patients (14). Specialized nipple and bottle kits used for feeding cleft patients include the Mead-Johnson Cleft Palate Feeder, the Pigeon Cleft Palate Nipple and Bottle, and the Special Needs Feeder (Haberman Feeder). These special bottles can be made available and demonstrated to the cleft patient's parents well in advance of their due date—during their prenatal educational appointment (14). Prenatal counseling regarding the use of these techniques is important for families to be well prepared for the challenges of feeding the cleft patient. Cleft patients without other medical issues requiring hospitalization are discharged home once able to ingest appropriate quantities of breast milk or formula to prevent malnutrition and dehydration, and the family is instructed to follow up in the cleft clinic in the week after discharge. Patients should return to their birth weight by their 2-week postnatal examination and should thereafter gain approximately 0.5 to 1 oz./day (14). Frequent reevaluations early in the patient's life ensure that the patient is monitored for any signs or symptoms of malnutrition or dehydration, which may require medical intervention.

ANATOMY AND CLASSIFICATION OF THE CLEFT DEFORMITY

Unilateral Cleft Lip Anatomy

The anatomy of the upper lip and nose is complex and involves several important structures: the nasal alae, the columella, the nasal septum, the philtrum of the upper lip, the wet and dry vermillion, the orbicularis oris muscles, and the oral commissures. These structures are affected differently in patients with unilateral and bilateral clefts. In the unilateral cleft, there is an imbalance of the lip/nasal morphology, causing the medial premaxillary segment to rotate externally and upward, while also causing internal and posterior rotation of the lateral minor maxillary segment (5). The orbicularis oris muscle is abnormally inserted into the anterior nasal spine at the base of the columella on the nonclefted side and the nasal alar base on the clefted side (5). The clefted side's lower lateral cartilage is typically flattened and displaced posterolaterally, and the middle crus (dome) of the lower lateral cartilage is separated from the noncleft middle crus (5). The caudal septum is frequently dislocated from the vomerine groove and displaced into the nonclefted nostril (5).

Bilateral Cleft Lip Anatomy

In patients with a complete bilateral cleft lip, the premaxillary segment is positioned more anteriorly than in nonclefted patients, due to its lack of fusion with the lateral maxillary segments. The prolabium does not contain orbicularis oris muscle, and the vermilion and white roll are significantly deficient. The nasal deformity is fairly uniform and consists of flared nasal alar bases, a wide and flat nasal tip, and a short columella (5). Incomplete bilateral clefts have similar features, although the protrusion of the premaxillary segment is less severe than that of patients with a complete deformity.

Palatal Anatomy

The palate may be divided into the primary palate and the secondary palate; the primary palate (premaxilla) is located anterior to the incisive foramen, and the secondary palate located posterior to the incisive foramen (15). The secondary palate is further subdivided into the hard palate posterior to the incisive foramen and the velum, or soft palate. The velum contains five paired muscles: the muscularis uvulae, the palatoglossus, the palatopharyngeus, the levator veli palatini (LVP), and the tensor veli palatini (TVP) (16). The muscularis uvulae originates anteriorly on the tensor aponeurosis in the midline and extends posteriorly in the midline to the uvula (16). The palatoglossus muscle originates from the dorsolateral aspect of the tongue and extends within the anterior tonsillar pillar to insert into the velum (15,16). The palatopharyngeus muscle originates from the superior pharyngeal constrictor and extends within the posterior tonsillar pillar to insert into the velum, dividing into a superior oral head and an inferior nasal head, both enveloping the LVP muscle within the velum (16). The TVP originates from the eustachian tube (ET) and greater wing of the sphenoid, coursing anteriorly around the hook of the hamulus and inserting medially upon the tensor aponeurosis (15). In Huang's anatomic dissection of the paratubal muscles, the LVP was found to originate from the junction of the bony and cartilaginous portions of the eustachian tube, rather than the quadrate region of the petrous temporal bone as previously described (17).

Clefts of the soft palate alter the ability of the velum to obturate the nasopharyngeal port and have a relatively predictable anatomic structure. Rather than coursing medially to coalesce in the midline of the middle third of the velum,

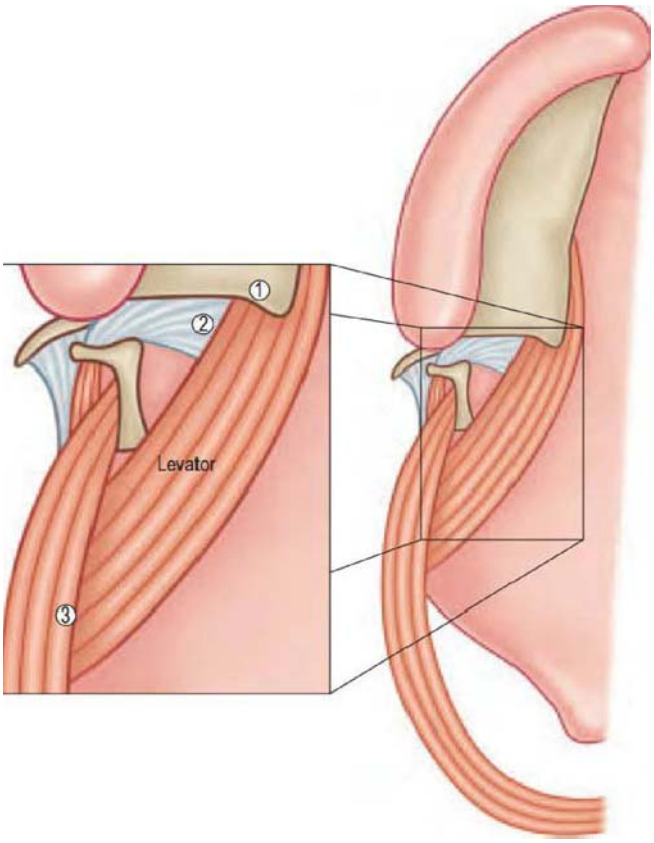

Figure 103.2 The three abnormal insertion points of the levator palatini muscle—*1.* posterior edge of the hard palate, *2.* TVP aponeurosis, *3.* superior pharyngeal constrictor muscle. (From Losee JE, Smith D. Cleft palate repair. In: Butler CE, ed. *Head and neck reconstruction.* Philadelphia, PA: Saunders Elsevier, 2009:275, with permission.)

the paired LVP muscles follow a more anterior direction to insert upon the posterior edge of the hard palate. In patients with cleft palate, the LVP has three abnormal attachments: the superior pharyngeal constrictor, the tensor aponeurosis, and the posterior edge of the hard palate (15) (Fig. 103.2).

Anatomical Classification Systems

Multiple classification systems for CL/P have been proposed; each has its own merits and limitations. These systems range from simple lettering systems, such as Kriens' LAHSHAL system, to Millard's modification of Kernahan "striped-Y" (18). At our institution, we prefer to use the LAHSHAL system for clefts of the lip and alveolus, given its simplicity and ability to address complete, incomplete, and submucous cleft anatomy. The LAHSHAL descriptive system represents the patients Lip, Alveolus, Hard palate, Soft palate, Hard palate, Alveolus, Lip anatomically from right to left. It is convenient in that it allows the clinician to categorize the cleft with the use of capital letters to signify a complete cleft, small letters to signify an incomplete cleft, an asterisk to signify a submucous or microform cleft, and an "X" to signify a normal structure. Hence, a left-sided complete cleft of the lip, alveolus, hard palate, and soft palate would be: "XXXSHAL." An incomplete right-sided lip and cleft of the soft palate would be: "lXXsXXX" (Fig. 103.3). For similar reasons, we utilize the Veau classification system for clefts affecting only the palate. The Veau classification system for cleft palate deformities is also simple and convenient: Veau I clefts involve only the soft palate; Veau II clefts involve the hard and soft palate; Veau III clefts are unilateral complete clefts of the alveolus, hard, and soft palate; and Veau IV clefts are bilateral complete clefts of the alveolus, hard, and soft palate. Often the Veau III and IV clefts are associated with clefts of the lip (15).

SURGICAL MANAGEMENT OF THE PRIMARY DEFORMITY: SEQUENCING AND TIMING

There is no "cookbook" approach to cleft care, and each patient requires an individualized treatment plan. As an example, patients presenting to large cleft centers may live several hours away. This distance may present a logistical barrier to the use of innovative presurgical treatments, like presurgical infant orthopedics (PSIO), that often require weekly visits for up to several months. If this is the reality, then prior to definitive surgery for the lip and nose, a lip adhesion procedure may be considered as an alternative to PSIO. While there is a general "timeline" for the overall surgical care of these patients, an individualized approach is preferred, taking into consideration the patient's and family's particular needs.

Presurgical Infant Orthopedics

Presurgical infant orthopedics (PSIO) is a treatment started early in a cleft patient's life. The goal of PSIO is to realign the clefted maxillary shelves, bring the widely separated lip margins together, and reshape the nose, "setting-up" and facilitating the surgical reconstruction. PSIO modalities include active techniques such as the Latham appliances or passive techniques such as lip taping or nasoalveolar molding (NAM). NAM, a passive form of PSIO, has gained popularity among cleft centers and is generally started in patients with complete unilateral or bilateral clefts at approximately 1 week of age. Weekly evaluations with modification of the NAM device to mold the lip, alveolus, and nasal ala are continued until the patient is 3 to 4 months of age, immediately prior to definitive repair of the cleft lip/nose deformity. In patients with complete clefts who are not candidates for NAM, lip adhesion surgery may be performed at approximately 1 to 2 months of age. Originally described in 1960 by Johansson and Olson (1960), staged lip repair with lip adhesion as the initial procedure has been utilized in patients with wide complete clefts in order to convert

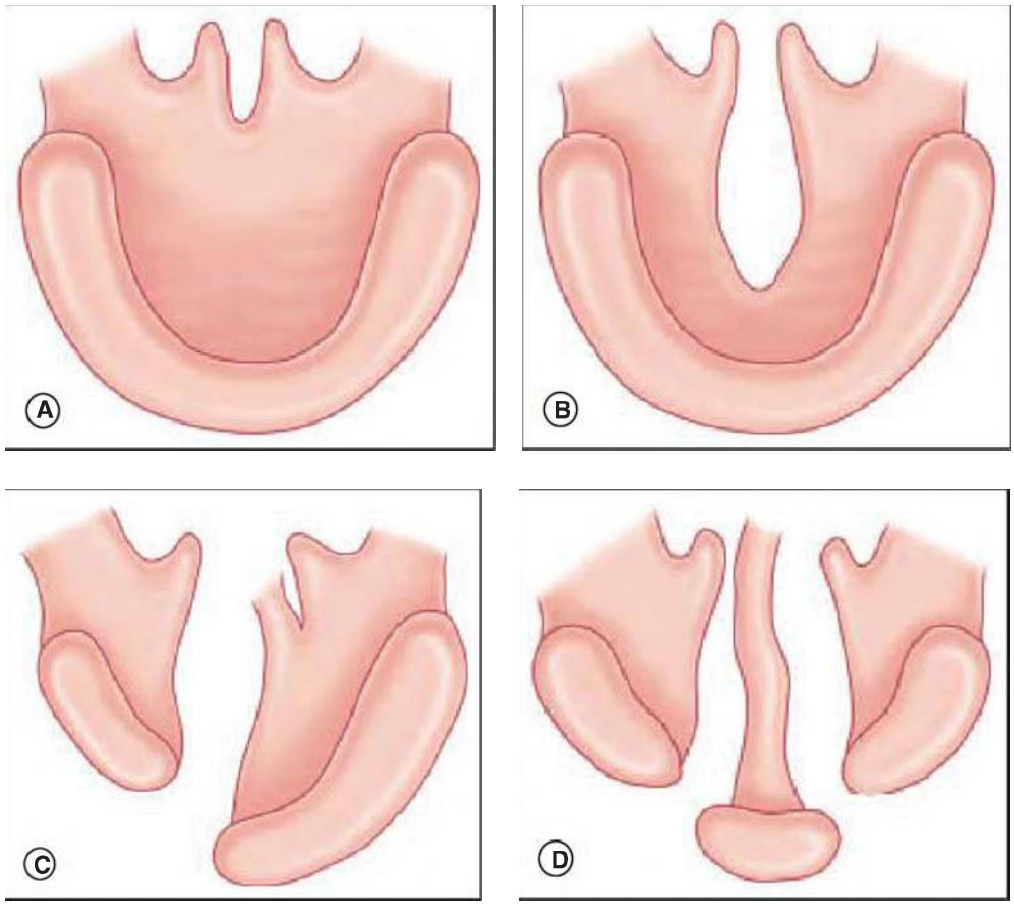

Figure 103.3 Veau classification system for cleft palate. **A:** Veau I cleft of soft palate. **B:** Veau II cleft of soft and hard palates. **C:** Veau III cleft of unilateral hard and soft palates. **D:** Veau IV bilateral cleft of hard and soft palates. (From Losee JE, Smith D. Cleft palate repair. In: Butler CE, ed. *Head and neck reconstruction.* Philadelphia, PA: Saunders Elsevier, 2009:276, with permission.)

these defects into a more easily managed "incomplete" defect (19). Lip adhesion places the soft tissue elements of the cleft in a more normal position and allows the lip to exert guiding forces along the major and minor maxillary segments, thereby reducing the size of the cleft and improving alignment. Patients undergoing staged cleft lip repair typically undergo definitive cleft lip/nose repair at 4 to 6 months, in order to allow the lip adhesion to mature, and for the tension from the adhesion to passively bring the major and minor cleft maxillary segments together.

Cleft Lip and Nose Repair

At our institution, the primary repair of a unilateral or bilateral cleft lip is performed in otherwise healthy infants at approximately 3 to 6 months of age, when the infant has grown enough to make surgical repair safer for the patient. In the past, many surgeons have used the "rule of 10s" as a guideline for the timing of primary repair—10 lb, 10 g/dL hemoglobin concentration, and 10 weeks of age (20). At the time of cleft lip repair, the child should be healthy and well nourished, without signs of active illness, in order to safely undergo anesthesia.

Cleft Palate Repair

Primary repair of the cleft palate deformity is generally undertaken at 9 to 12 months. As the development of normal speech is the primary outcome of palatoplasty, delaying palatal repair beyond 15 to 18 months of age is generally not recommended unless the patient has other developmental or medical concerns.

Speech Surgery

Speech surgery to address velopharyngeal insufficiency (VPI) may be carried out at any time following cleft palate repair, once the diagnosis has been confidently made by an experienced speech pathologist on the cleft team. The speech pathologist periodically monitors the patient's speech for the development of VPI and then makes the

appropriate recommendations for secondary speech surgery for patients with VPI before compensatory changes make speech improvement challenging.

Secondary Surgery

At each cleft team visit, an assessment of the repaired lip and nose is made to categorize any secondary deformity. Secondary, "touch up" surgical procedures are common, being the "rule" and not the "exception." Typically, they are first considered prior to the patient entering kindergarten. Pulsed-dye laser therapy may also be of benefit for scars that remain overly hyperemic. Later lip revisions and definitive septorhinoplasty may be entertained in adolescence. Both the patient and family, in consultation with the surgeon, guide the timing and appropriateness of these secondary procedures.

Alveolar Bone Grafting

Alveolar bone grafting is typically performed in mixed dentition just prior to eruption of the permanent maxillary canines around 6 to 9 years of age. Oronasal fistula repair and alveolar bone grafting is performed before the eruption of the permanent canine in order to provide stable alveolar bone for the tooth, thereby maximizing its chances for long-term retention.

Orthognathic Surgery

The correction of maxillomandibular discrepancies can be performed in the growing child if the class III malocclusion is severe and symptomatic; this is usually accomplished with distraction osteogenesis in this age group. Classic orthognathic surgery for the cleft patient is reserved for patients who have completed skeletal growth. Options for patients with significant maxillary retrusion include LeFort I osteotomy in patients with mild to moderate deformities and LeFort I osteotomy and maxillary distraction osteogenesis in patients with severe deformities without mandibular prognathism. In the unusual cleft patient with maxillary retrusion with concomitant mandibular prognathism, double jaw surgery with mandibular procedures such as bilateral sagittal split osteotomy (BSSO), may be indicated to restore a normal facial profile.

Cleft Rhinoplasty

The primary cleft lip–nasal deformity was historically treated only in a delayed fashion, avoiding any nasal surgery during primary lip repair (21). More recent experience has shown that concurrent primary lip and nasal repair is a safe and effective practice and is an approach utilized by most cleft surgeons today (21,22). Secondary cleft septorhinoplasty is typically performed in early adolescence or following orthognathic surgery.

SURGICAL MANAGEMENT OF THE PRIMARY DEFORMITY: TECHNIQUE

Presurgical Infant Orthopedics: Nasoalveolar Molding

Nasoalveolar molding (NAM) has been utilized for patients with both unilateral and bilateral cleft lip/nasal deformities with considerable success. Several studies by Grayson et al. have demonstrated the remarkable ability of this technique in facilitating both the approximation of the complete cleft lip deformity and improving the deformed cleft side lower lateral cartilage (23,24). In the New York University NAM protocol, patients with a complete cleft lip/nose deformity are treated with NAM for approximately 4 months, beginning at 1 week of age (23). Patients undergoing NAM treatment must have an impression taken of the alveolar segments, and a custom-made NAM splint is made from this mold. Patients must return to the office weekly for NAM device adjustment and to examine the child for any potential complications of treatment, including pressure sores, malalignment, or lack of progress. A nasal conformer is added to the device once the alveolar cleft measures less than 5 mm in width, and is used to mold the collapsed nasal ala (23). A 2008 anthropometric study by Grayson et al. demonstrated that patients who were treated with presurgical NAM demonstrated improved nasal tip projection, nasal alar symmetry, and decreased columellar deviation when compared to patients who underwent cleft repair without NAM (23).

Lip Adhesion

Lip adhesion surgery is typically performed in infants before 3 months of age. In patients with a unilateral cleft, the lip is marked with methylene blue as in unilateral cleft lip repair. By clearly marking these structures, the surgeon can place the incisions for the adhesion away from structures used in the definitive lip repair. "Book flap" incisions for the adhesion are placed within the mucosa of the lateral and medial lip elements, approximately 6 to 8 mm inferior to the nostril sill (19). A buccal sulcus incision on the lateral lip element is designed so that supraperiosteal dissection of the lateral lip element and alar base may adequately mobilize the lateral lip and ala. This incision is extended superiorly onto the inferior turbinate, along the pyriform aperture to release and advance the lateral lip and nose element (19). The lower lateral cartilage on the cleft side and nasal tip may be dissected through this incision if the surgeon desires to reposition the lower lateral cartilage at this stage. Once the incisions have been made and the lateral lip element mobilized, a horizontal mattress 3-0 polypropylene suture is placed across the cleft to bring the medial and lateral lip elements together (19). Muscle and mucosal sutures are placed to approximate the orbicularis oris muscle and lip margin mucosal flaps.

For patients with bilateral cleft lip and nose deformity, the adhesion procedure is carried out in a similar fashion as in a unilateral cleft lip and nose deformity, widely mobilizing the lateral lip elements and bringing them toward the midline with the 3-0 polypropylene horizontal mattress stitch. The lower lateral cartilages are dissected and mobilized through the buccal sulcus incision, and the mucosal flaps are then sutured to each other to complete the adhesion. In both unilateral and bilateral lip adhesion procedures, nasal conformers are placed to help support the repositioned lower lateral cartilages and are left in place until the time of definitive lip repair.

Unilateral Cleft Lip and Nose Repair

Several types of unilateral cleft lip and nose repair have been extensively described; however, variations on the classic Millard rotation–advancement technique are the most commonly utilized repair (25). Important landmarks of the upper lip–rotation flap are marked with methylene blue (Figs. 103.4 and 103.5):

1. The nadir of Cupid's bow
2. The peak of Cupid's bow on the noncleft side
3. The distance between 1 and 2 is measured with a Castroviejo caliper; this distance is then transposed to the proposed peak of Cupid's bow on the cleft side.

Figure 103.4 Key anatomic landmark points for marking a unilateral cleft lip repair. Note the principal anatomic points: *1.* the nadir of Cupid's bow; *2.* the peak of nonclefted side of Cupid's bow; *3.* the peak of clefted side of Cupid's bow; *4.* the desired point for the peak of Cupid's bow on the lateral lip element, where the white roll loses its fullness. (From Salyer KE, Cheng AM, Michenzi JW, Genecov E. Unilateral cleft lip/nose repair. In: Kischner RE, Losee JE, eds. *Comprehensive cleft care.* New York, NY: McGraw-Hill, 2009:310, with permission.)

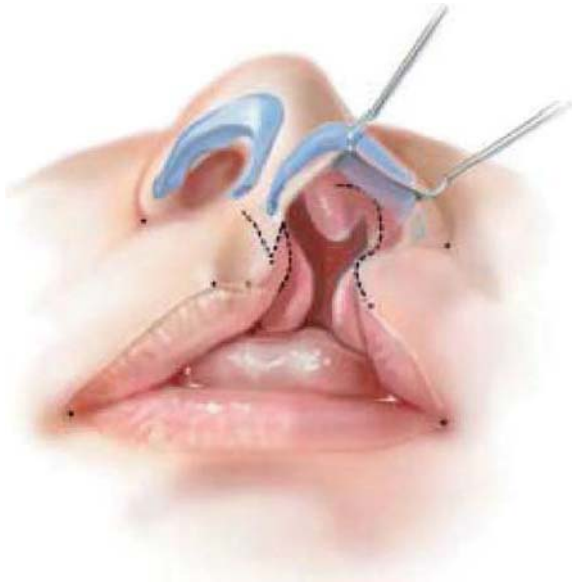

Figure 103.5 Incisions utilized for unilateral cleft lip repair. Note the incision along the new, desired philtral column and the creation of a C-flap. Note cleft side incision along margin of cleft, extending onto inferior turbinate, to allow for left nasal alar mobilization. (From Salyer KE, Cheng AM, Michenzi JW, Genecov E. Unilateral cleft lip/nose repair. In: Kischner RE, Losee JE, eds. *Comprehensive cleft care.* New York, NY: McGraw-Hill, 2009:311, with permission.)

The height of the philtral column on the noncleft side is measured with 26-gauge surgical wire and is then transposed to the cleft side's proposed philtral column. A small back cut from the apex of the philtrum down to the noncleft philtral column is marked. The lateral lip element–advancement flap markings are then made:

4. The vermilion–cutaneous junction of the desired peak of Cupid's bow where the white roll and lateral lip element begin to lose their fullness.
5. The surgical wire is used to mark distance for the medial incision of the advancement flap as it courses cephalad toward the nasal sill.

The red line separating wet and dry vermilion is marked on the medial and lateral upper lip elements, and the dry vermilion is measured with a Castroviejo caliper. If the medial lip element dry vermilion is deficient, a triangular flap of dry vermilion can be designed on the lateral lip element to augment this deficient height.

The medial lip element–rotation flap is incised, beginning at the apex of the philtrum, down along the philtral column marked on the cleft side, across the white roll and into the dry vermilion. The incision is continued vertically to the upper gingivobuccal sulcus. The orbicularis is dissected off its abnormal attachment to the anterior nasal spine, and the upper lip is mobilized in a supraperiosteal plane along the maxilla and pyriform aperture, allowing it to be rotated inferiorly, balancing Cupid's bow.

The lateral lip element–advancement flap incision is made in a similar fashion and is carried vertically into the

nose and onto the anterior surface of the inferior turbinate. Supraperiosteal dissection is continued laterally to the pyriform aperture, mobilizing the abnormally tethered alar base, allowing medial transposition of the nasal ala and lateral lip element–advancement flap. A buccal sulcus incision is made to further allow for medialization of the lateral lip element–advancement flap. The free cut edge of the orbicularis oris muscle is dissected free from the overlying skin and underlying mucosa and is sutured to the muscle of the medial lip element. Once the muscle has been repaired, the external skin of the upper lip is repaired. The tip of the lateral lip element advancement flap is inset into the back cut of the medial lip element–rotation flap.

Attention is turned to the nose, and a nasal rim incision is made on the cleft side, so the lower lateral cartilage may be completely mobilized from the overlying skin. This dissection is carried over the nasal dorsum and over to the contralateral side of the nose. Absorbable sutures are used to reapproximate the genua of the lower lateral cartilages and resuspend the cleft side lower lateral cartilage. Closure of the nasal floor completes the repair, and a silicone nasal conformer is placed.

Bilateral Cleft Lip and Nose Repair

Variations of the Mulliken repair are widely utilized in patients with a bilateral cleft lip and nose deformity (Fig. 103.6). First, the upper lip landmarks and proposed incisions are marked. The subnasale is marked, as is the desired nadir of the new Cupid's bow. The vertical distance between these two points in a 3-month-old infant is typically 6 to 8 mm. The base of the philtrum and the proposed peaks of Cupid's bow are then marked (26). The lateral lip elements are then marked where the fullness of

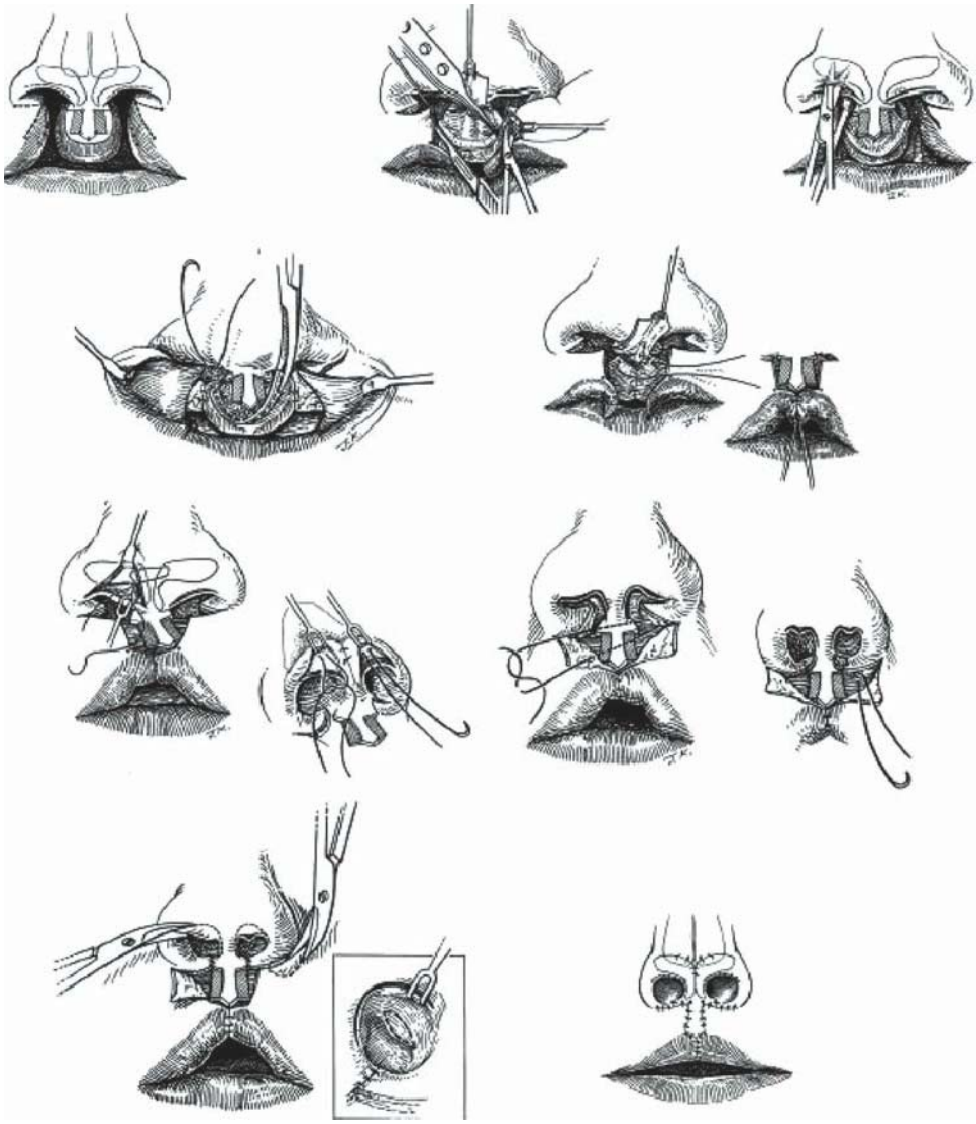

Figure 103.6 Mulliken method of single-stage bilateral nasolabial cleft repair, utilizing a semiopen approach to the nasal tip cartilages through bilateral nasal rim incisions. (From Mulliken JB. Primary repair of bilateral cleft lip and nasal deformity. *Plast Reconstr Surg* 2001;108(1):186, with permission.)

the white roll and lip begins to fade. As the white roll of the reconstructed Cupid's bow will come from the lateral lip elements, a distance of 2 mm is marked down each of the lateral lip elements (26). This incision will turn down a segment of white roll and vermilion to form Cupid's bow and the central tubercle of the upper lip.

Dissection begins on the prolabium, and the new philtrum is incised and raised in the subcutaneous space to the level of the subnasale. The vermilion of the premaxilla is placed beneath the elevated philtrum and on to the raw surface of the premaxilla. Next, the lateral lip element incisions are made, extending into the buccal sulcus, and dissection in the supraperiosteal plane is undertaken to mobilize the lateral lip element flaps. The buccal sulcus incisions are extending into the nose and onto the inferior turbinate, again allowing for complete mobilization of the abnormally tethered alar bases. The orbicularis oris muscle is then dissected free for several millimeters from the free edges of the skin and mucosal incisions.

Once dissection is complete, the mucosal closure of the lip is performed with absorbable sutures. This is followed by precise orbicularis oris repair to realign the pars peripheralis and pars marginalis in an anatomically correct position in the midline, posterior to the philtral flap, tacking the superior aspect of the muscular closure to the anterior nasal spine.

The tip of the nose is degloved through nasal rim incisions. Interdomal sutures to reapproximate the genua of the lower lateral cartilages are placed, narrowing the nasal tip. In order to correct the widened the nasal base, an alar base cinch stitch is placed through both alar bases and tightened to correct the distance between the alar bases. The nostril sills are then repaired. Judicious trimming of the soft triangles is required to remove excess tissue in this area and create a more round nostril aperture. These incisions are then repaired with fine absorbable suture (26).

Cleft Palate Repair

There are many different approaches to both hard and soft palate repair. Options for soft palate repair include both straight line and Z-plasty techniques with or without intravelar veloplasty. For repair of hard palate defects, unipedicled or bipedicled mucoperiosteal flaps are utilized (4). Patients typically undergo palatoplasty at 9 to 15 months of age, depending upon their physical status and other comorbidities.

Furlow Double Opposing Z-Plasty

The Dingman retractor is gently placed to hold the mouth open and retract the tongue (Fig. 103.7). The proposed lateral relaxing incisions are marked in the crease where the cheek sidewalls meet the velum laterally, extending around the posteromedial aspect of the maxillary tuberosity and

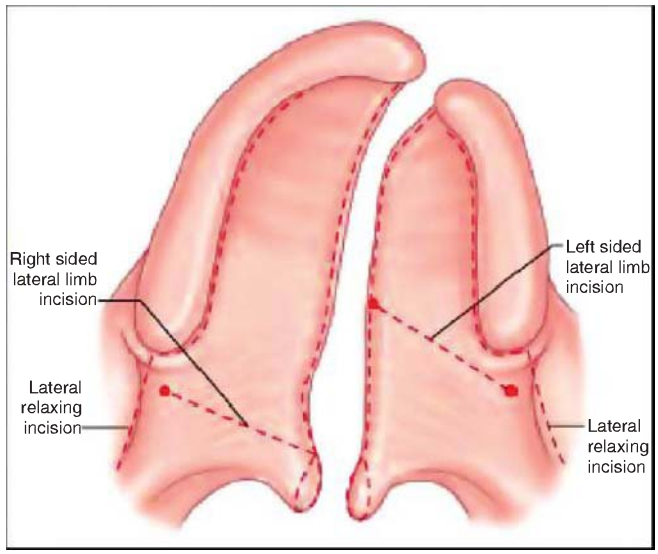

Figure 103.7 Standard incision markings for Furlow palatoplasty. (From Losee JE, Smith D. Cleft palate repair. In: Butler CE, ed. *Head and neck reconstruction.* Philadelphia, PA: Saunders Elsevier, 2009:279, with permission.)

onto the lingual surface of the hard palate. The hamulus is then palpated and marked, lying posterior to the maxillary tuberosity. Next, markings are placed at the hard/soft palate junction and base of the uvula. The medial aspects of the cleft margins are marked, extending from the hard–soft palate junction to the uvular bases, taking care to "cheat" onto the oral surface by 1 mm in order to recruit mucosa for nasal lining closure. The posteriorly based oral musculomucosal flap is marked on the patient's left side, from the hamulus to the junction of the hard and soft palate. The anteriorly based oral mucosal flap on the right side is marked from the uvular base to hamulus. Care is taken to leave an adequate mucosal bridge between these incisions and the relaxing incisions, to preserve vascularity to the flaps.

Next, the velum is infiltrated with dilute epinephrine, and the uvular halves are demucosalized with dissecting scissors. The left-sided posteriorly based musculomucosal flap is incised along the marked lines. Deeper dissection separates the soft palate musculature from the underlying nasal mucosa. Care must be taken to ensure that the three abnormal attachments of the levator are released: the posterior edge of the hard palate, the tensor aponeurosis, and the superior pharyngeal constrictor (15). These maneuvers allow the left-sided posteriorly based musculomucosal flap to be transposed from its anteroposterior orientation to a transversely oriented posterior position.

The right-sided anteriorly based oral mucosal flap is then incised along the cleft margin and then the uvular base to the hamulus. The underlying soft tissues are then retracted so that they may be divided with dissecting scissors until the aponeurosis of the palatopharyngeus

and palatoglossus muscles is identified and preserved. Submucosal dissection is continued laterally, taking care to include the subcutaneous fat and mucosal glands with the mucosal flap to preserve vascularity. The abnormal connection between the levator muscle and posterior edge of the hard palate is identified and then divided 2 to 3 mm posteriorly, to preserve a cuff of nasal mucosa along the posterior edge of the hard palate for nasal lining repair. This dissection is carried posterolaterally to the point where the levator exits the skull base beneath the superior constrictor muscle.

Bilateral relaxing incisions are made with a scalpel; scissors are then inserted into the posterior aspect of each relaxing incision with the tips oriented medially. These are gently spread in the space of Ernst to release the overlying mucosal bridge. Within these relaxing incisions, the tendon of the TVP muscle should be identified, isolated, and divided. The soft tissues medial to the hamulus and posterior to the hard palate are divided with dissecting scissors to complete the mobilization of the velar flaps.

The hard palate mucoperiosteal flaps are then incised and mobilized with a Blair elevator, taking care to identify and preserve the neurovascular pedicle as it exits the greater palatine foramen posterolaterally. Gentle stretching of the periosteum surrounding the pedicle is often necessary to fully mobilize the hard palate flaps. The nasal mucosa is dissected from the undersurface of the maxillary shelves along the medical bony edge of the cleft with a Woodson elevator. If necessary, vomerine mucoperiosteal flaps are used for nasal lining closure of the hard palate.

The soft palate nasal flaps are then made. The left-sided anteriorly based nasal mucosal flap is then designed and incised from the uvular base to the origin of the LVP posterolaterally as it exits the skull base. The right-sided posteriorly based nasal musculomucosal flap is incised at a point just posterior to the junction of the hard and soft palate, extending posterolaterally to the origin of the LVP as it exits the skull base, leaving a cuff of nasal lining along the posterior edge of the hard palate for nasal lining repair. The nasal lining flaps are transposed in a Z-plasty fashion and inset. In selected cases where nasal lining closure is tenuous or impossible, thin acellular dermal matrix as an onlay repair may be utilized (27). Care is taken to avoid suturing the graft to the levator sling; securing sutures are placed in the nasal lining, tensor aponeurosis, and posterior edge of the velum. Once the nasal lining repair is complete, repair of the uvula is performed. The oral flaps are then transposed in an opposing Z-plasty fashion, bringing the left-sided posteriorly based musculomucosal flap into transverse orientation, completing the velar reconstruction. The hard palate mucoperiosteal flaps are inset in the midline with absorbable suture and secured along the anterior edge of the lingual surface of the alveolar incisions (Fig. 103.8).

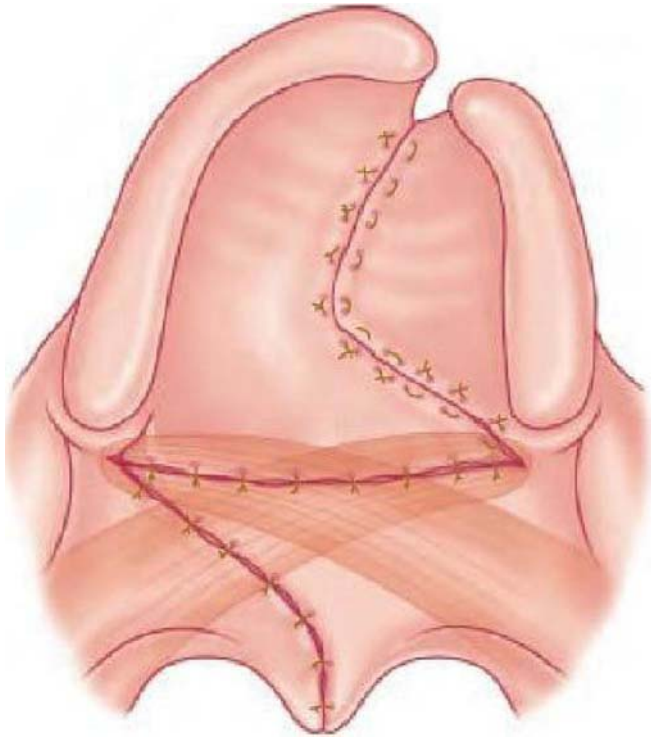

Figure 103.8 Palate repaired with Furlow technique. Note the transverse orientation of the LVP muscles. (From Losee JE, Smith D. Cleft palate repair. In: Butler CE, ed. *Head and neck reconstruction.* Philadelphia, PA: Saunders Elsevier, 2009:287, with permission.)

Straight-Line Repair with Intravelar Veloplasty

Straight-line cleft palate repair with intravelar veloplasty is a technique also utilized by many surgeons (Fig. 103.9). The principles of straight-line soft palate repair in intravelar veloplasty are similar to Furlow palatoplasty in that the crucial element of the procedure is to restore the levator sling musculature to a transverse orientation from an abnormal anteroposterior orientation in the unrepaired state.

The medial incisions are made along the cleft margin, beginning at the uvular base, extending anteriorly along the length of the cleft. Sharp dissection is performed in the submucosal plane, taking care to include the subcutaneous fat and mucosal glands in the oral mucosal flaps. The oral mucosal flaps are widely undermined to the lateral aspects of the velum in order to completely expose the levator muscles bilaterally. Wide dissection is then carried out between the levator muscles and the nasal lining, separating the velum into three distinct layers. The LVP muscles are then carefully released from their abnormal attachments: the posterior edge of the hard palate, the tensor aponeurosis, and the superior pharyngeal constrictor. The nasal lining along the cleft is repaired, utilizing acellular dermal matrix to augment the closure if there are any areas of tenuous closure or mucosal defects that cannot be primarily closed (27). Once the nasal mucosal layer has been

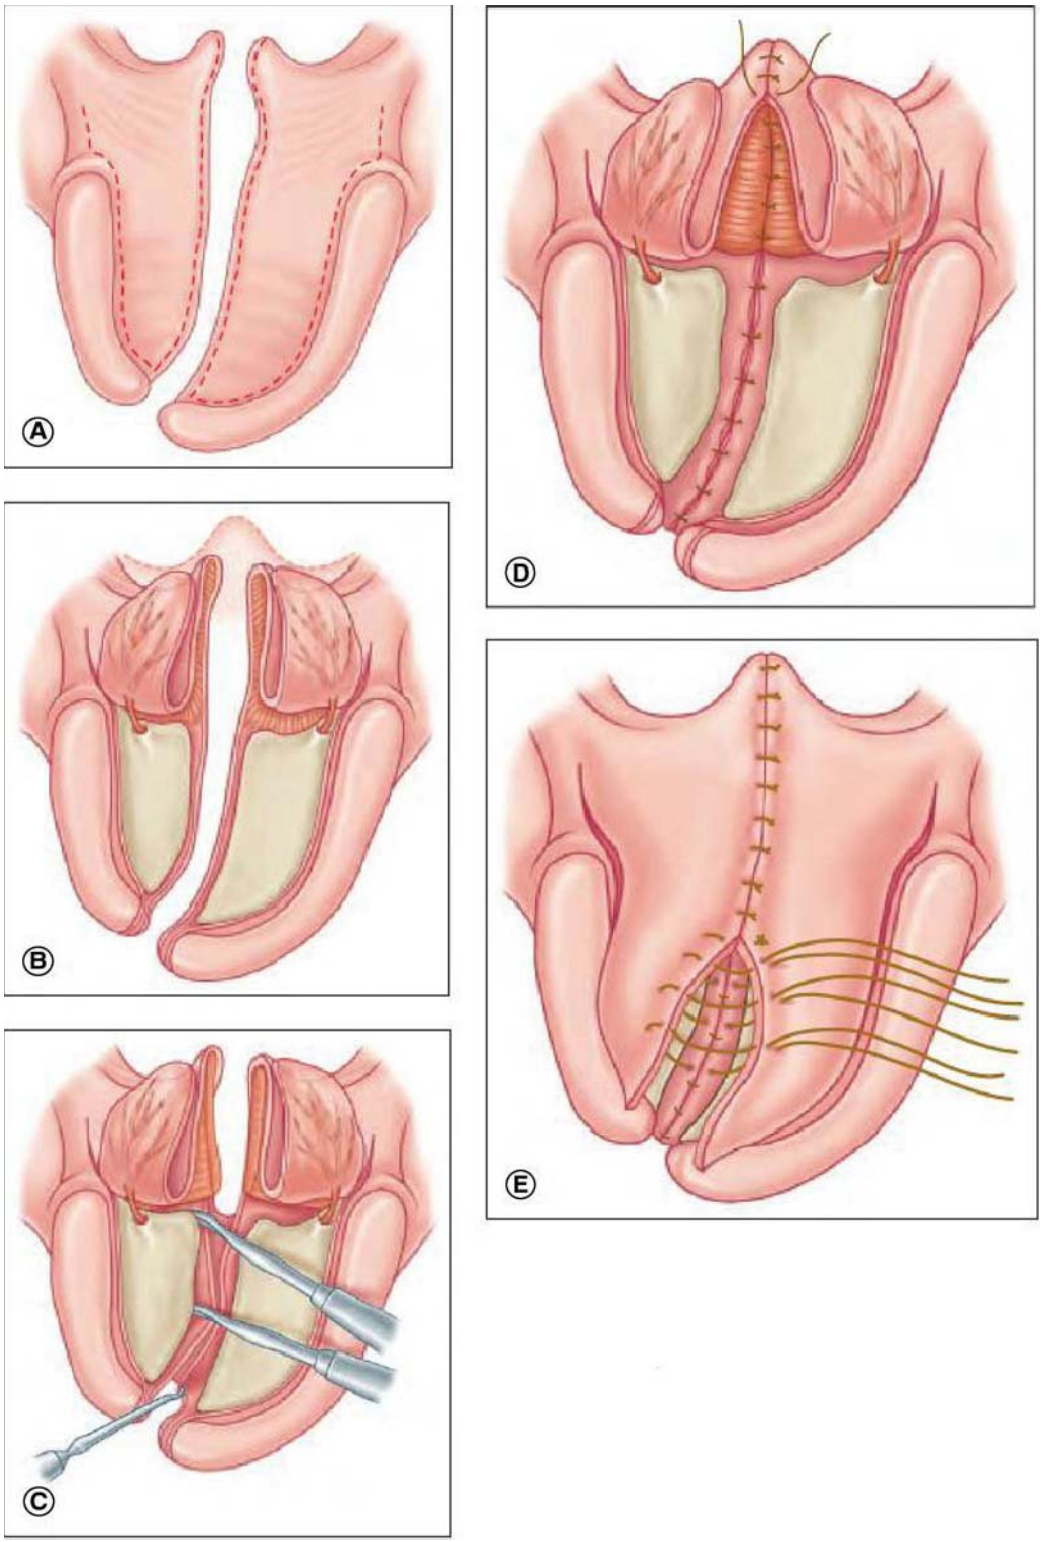

Figure 103.9 **A:** Design of bilateral unipedicled hard palate mucoperiosteal flaps. **B:** Dissection of bilateral unipedicled hard palate mucoperiosteal flaps, each containing the greater palatine artery on each side. **C:** Dissection of nasal lining from posterior edge of the hard palate. **D:** Repair of nasal lining along edges of hard and soft palate cleft. **E:** Repair of oral lining along edges of hard and soft palate cleft. repaired, the LVP muscles are transposed posteriorly into a posterior transverse orientation, where they are properly tensioned and sutured together in the midline. After levator muscle closure, the oral mucosa is closed with interrupted absorbable sutures.

Speech Surgery

Velopharyngeal insufficiency (VPI) after cleft palate repair is reported to occur in approximately 10% to 20% of patients (28). Many authors advocate the use of pharyngeal flap surgery in patients with poor palatal motion, a large central velopharyngeal port gap, and good lateral wall motion (29). Sphincter pharyngoplasty is typically used in patients with good palatal motion, a small central velopharyngeal gap, and poor lateral wall motion (28–31). Conversion to furlow palatoplasty has also gained favor as a technique utilized to correct VPI in patients who have previously undergone straight-line palatoplasty. Patients selected for secondary speech surgery often undergo tonsillectomy and adenoidectomy procedure 6 weeks in advance of their speech surgery in order to remove tissues that can cause significant obstruction of the velopharyngeal ports, decreasing the risk of hyponasality and possible obstructive sleep apnea (31).

For pharyngeal flap surgery, we prefer the modified Hogan technique. With this technique, the raw surface of the superiorly based pharyngeal flap is covered with nasal mucosal lining turndown flaps (32). The velum is incised in the midline, ending the incision just posterior to the junction of the hard and soft palate. Next, the nasal mucosa lining turndown flaps, pedicled on the posterior free edge of the velum, are incised and dissected free from the nasal side of the palatal musculature. A superiorly based posterior pharyngeal flap is developed on the posterior pharyngeal wall, setting the base of the flap superior to the level of estimated velopharyngeal closure and allowing for adequate lateral port size bilaterally. The pharyngeal flap is then elevated off the prevertebral fascia and inset into the velum with absorbable sutures. The nasal lining flaps are turned down to line the raw undersurface of the inset pharyngeal flap and are secured to the base of the elevated flap with absorbable sutures. Watertight mucosal closure proceeds from posterior to anterior, completing the procedure.

In patients undergoing sphincter pharyngoplasty, the posterior tonsillar pillars with underlying palatopharyngeus muscle are dissected to create superiorly based musculomucosal flaps. Once these flaps are elevated, they are transposed superomedially and inset transversely, high on the posterior pharyngeal wall at the estimated level of velopharyngeal closure, thereby creating a smaller velopharyngeal port (31).

Alveolar Bone Grafting

Reconstruction of the cleft maxillary and alveolar defect is of great importance in treating cleft patients. Approximately 20% to 30% of cleft patients develop significant dentofacial abnormalities, and may benefit from orthognathic surgery during late adolescence; the restoration of a one-piece maxilla with alveolar bone grafting greatly facilitates this process (33,34). In addition to facilitating orthognathic treatment, repair of the alveolar defect and oronasal fistula eliminates nasal fluid regurgitation and improves oral hygiene and provides bone support for the dentition.

Cleft patients are radiographically evaluated for dental development while in mixed dentition and undergo bone grafting of the maxillary and alveolar bone defect prior to the eruption of the permanent lateral incisor and canine (33). Patients benefit from presurgical orthodontic treatment to appropriately expand their maxillary dental arch and optimize the position of the teeth bordering the cleft.

Alveolar bone graft surgery begins by raising anterior gingival mucoperiosteal flaps on either side of the cleft. Wide subperiosteal dissection is performed to expose the edges of alveolar and maxillary defect. The oronasal fistula is taken down and repaired, creating a mucosal pocket, with its tip at the incisive foramen and its base at the anterior alveolus and maxilla. If there is a deficiency of nasal mucosa along the base of the defect, human acellular dermis may used to close the defect (27). A separate surgical setup is utilized to harvest iliac crest cancellous autograft, and the graft is packed densely into the cleft defect, and the gingival mucoperiosteal flaps are closed over the graft, completing the repair.

Orthognathic Surgery

Twenty to thirty percent of cleft patients will have severe maxillary retrusion and an angle class III dentofacial deformity unable to be corrected by standard orthodontic treatment (33). Subperiosteal dissection of the midface and restriction by postoperative scar tissue have been proposed as potential etiologies for this deformity, although in a caprine fetal model study by Weinzweig et al., animals that did not undergo cleft palate repair also demonstrated some degree of midface hypoplasia (35). It is important that a multidisciplinary cleft team routinely evaluates cleft patients with midface deformities in order to optimize select patients for orthognathic surgery.

Patients with a class III dentofacial deformity, but without mandibular prognathism, may benefit from a LeFort I osteotomy and advancement, which can be performed as a one-step operation in patients who require a small advancement or with distraction osteogenesis in patients who require advancement in excess of 7 mm. Kumar et al. demonstrated decreased relapse rates in patients with severe class III dentofacial abnormalities who underwent LeFort I osteotomy and distraction osteogenesis (15%) when compared to traditional one-step LeFort I osteotomy and advancement (63%) (34). Other patients with class III dentofacial deformities, in combination with prognathism, may require double jaw surgery—LeFort I with BSSO—to correct the problem.

In cleft patients being evaluated for dentofacial deformities, cephalometric evaluation and dental models should be obtained for preoperative planning. Presurgical orthodontic preparation for the orthognathic movement desired is often required. Once these preparations are complete, the patient may undergo surgical manipulation of the jaws.

Patients undergoing LeFort I osteotomy and advancement are nasotracheally intubated and access to the maxilla is obtained through upper gingivobuccal sulcus incisions (Fig. 103.10). It is important to recognize that the central area of the gingivobuccal sulcus may be the only blood supply to the premaxillary segment in bilateral cleft patients, and this mucosa should be preserved. Once the maxilla has been exposed, the pyriform aperture is dissected free of nasal mucosa, extending the dissection along the floor of the nose posteriorly. Lateral dissection of the maxilla is then performed until the pterygomaxillary fossa is encountered, allowing access to the pterygomaxillary junction. Once maxillary dissection is complete, a high osteotomy is designed bilaterally along the anterior maxilla from the zygomaticomaxillary buttress to the pyriform aperture, staying 5 mm below the infraorbital foramen and nerve (33). The maxillary osteotomies are then cut with a reciprocating saw, and the vomer and septum are separated with an osteotome. Finally, pterygomaxillary junction osteotomies are performed with a curved osteotome, aiming the osteotome inferoposteriorly to avoid injury to the maxillary artery within the pterygomaxillary fissure. The maxilla is down fractured and hemostasis is obtained by packing the defect, methodically exploring each side for bleeding vessels and controlling these with bipolar cautery. Any large nasal lining rents are sutured with absorbable suture, and the maxilla is freely mobilized on its pedicle—the posterior mucosal attachments of the soft palate. Bony interferences along the posterior aspects of the lateral and medial walls of the maxillary sinuses are removed with a rongeur, and the surgical splint is used to guide the maxillary dentition into appropriate occlusion prior to the placement of plate fixation. In select cases with significant inferior placement of the maxilla, or in multipiece advancements, bone grafting may be required to increase stability of the construct. In distraction cases, the maxilla is returned to its original position, and internal or external distraction devices are applied to the maxilla. A nasal alar base cinch stitch is performed to decrease nasal base width, and the intraoral incisions are closed with absorbable sutures.

If a BSSO is required, bilateral mandibular rami are exposed with intraoral incisions along the anterior aspect of each ramus. Subperiosteal dissection is utilized to obtain wide exposure of both mandibular rami anteriorly, medially, and laterally. Once the mandibular ramus has been dissected, the sagittal split osteotomy is designed, beginning medially at two-thirds the height of the ramus, inferior to the coronoid process, and extending mesially along the external oblique ridge to the inferior border of the mandible. The osteotomy is completed with osteotomes and a bone spreader (33). Once bilateral osteotomies have been completed, the mandibular condyles are seated, and the distal segment is guided into position with the surgical splint to orient the mandible into the correct occlusal relationship with the maxillary dentition. Both the distal and proximal segments are then secured with a clamp, and mandibulomaxillary temporary fixation is achieved by

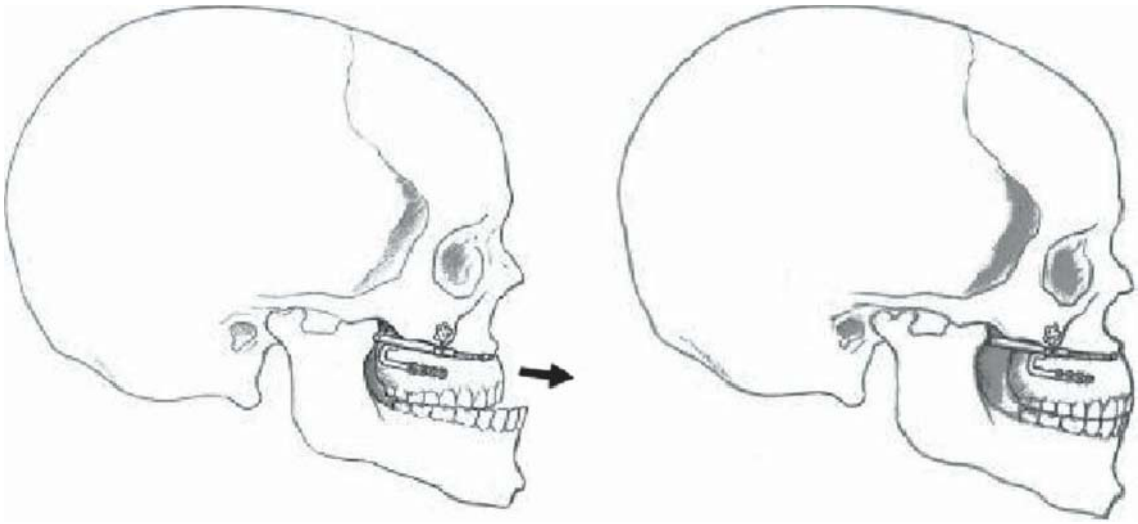

Figure 103.10 LeFort I maxillary advancement by distraction osteogenesis. (**Left**) Before distraction. (**Right**) After distraction of LeFort I segment. (From Kumar AR, Gabbay JS, et al. Improved outcomes in cleft patients with severe maxillary deficiency after LeFort I internal distraction. *Plast Reconstr Surg* 2006;117(5):1501, with permission.)

wiring of the jaws with the occlusal splint in place. Internal fixation is then performed to stabilize the mandibular construct, and the mandibulomaxillary fixation is released to confirm the occlusion.

Definitive Cleft Rhinoplasty

Repair of the cleft nose deformity presents a formidable surgical challenge, and surgical manipulation of the cleft nasal defect was frequently postponed until late adolescence. Recently, it has become standard for patients to undergo primary repair of the cleft nasal defect concurrently with cleft lip repair, understanding that many patients will still require definitive septorhinoplasty during adolescence. Patients wishing to improve nasal appearance and function must undergo complete facial analysis to determine their individualized functional and aesthetic goals. The nose is examined in detail to observe the specific deformities that may be present. In the unilateral cleft patient, these may include deviation of the columella to the noncleft side; inferior, posterior, and lateral displacement of the cleft side nasal ala; lateral displacement of the cleft side nasal alar base; nasal septal deviation toward the noncleft side; and hypertrophy of the inferior turbinate on the cleft side (21). Patients with a bilateral cleft deformity typically have a shortened columella, a broad and flat nasal tip, flat nasal alae, severely deformed lower lateral cartilages, and horizontally oriented nostrils (21).

Because of the amount of dissection required to address the asymmetries and contour abnormalities in cleft patients, many cleft rhinoplasties are performed using an open technique. While the surgical maneuvers required to correct each patient's deformity are individualized to the patient, most cleft patients will require submucous resection of the quadrangular cartilage of the septum, removal of abnormally situated portions of the vomer and perpendicular plate, reduction of a dorsal hump defect, nasal bone osteotomies, dorsal spreader grafts, a columellar strut cartilage graft for support, an alar rim graft on the cleft side in unilateral patients, and refinement of the nasal tip by repositioning the lower lateral cartilages (36). Internal and external nasal splints are placed to support the new nasal construct.

OTOLARYNGOLOGIC CONSIDERATIONS IN THE CARE OF THE CLEFT PATIENT

Ear Disease/Eustachian Tube Dysfunction

The relationship between middle-ear disease and a cleft palate is both structurally and physiologically tied to the ET. The ET connects the middle ear with the nasopharynx and depends on proper function of both the TVP and LVP musculature. A more detailed explanation of the anatomy and physiology of the ET is available elsewhere (37). Compared to adults, a noncleft child's ET has a larger bony component, is shorter, and is approximately 10 degrees off the horizontal hard palate. The orifice opening is oblique and both the lumen and the orifice opening of the ET are smaller (37).

The differences between the ET in a noncleft child compared to a child with a cleft palate have been well studied (37). The tube is shorter and there is a larger angle between the cartilage and the TVP. There are inherent changes to the cartilage and muscle as well. The cartilage is deformed and there is a greater cartilage cell density. There is less elastin at the hinge of the cartilage. Both the TVP and LVP muscles have less contractile tissue and more connective tissue (37). The relative position of the TVP causes baseline functional obstruction of the ET.

These differences in the anatomy and physiology of the ET are manifested clinically as chronic middle-ear disease. The theoretical "sequence" is that an unrepaired cleft causes obstruction at the nasopharyngeal end of the ET because of the baseline compression of the ET with impaired ability to open the ET due to abnormalities of its component parts described above. This obstruction induces negative middle-ear pressure, which leads to middle-ear mucosal swelling and eventual middle-ear fluid accumulation. The combination of the fluid accumulation and an obstructed isthmus leads to fluid stasis, increased fluid viscosity, and no clearance of the fluid. This sequence of events with the associated persistent middle-ear effusion (MEE) has been documented as early as the first month of life. Bluestone et al. studied 21 infants with an unrepaired cleft palate and found abnormal ET function to be ubiquitous (38). Fria et al. performed auditory brainstem response testing in a number of children with unrepaired cleft palate and found significant conductive hearing loss prior to tympanostomy tube (TT) placement, which was reversed after tube placement (39). Similarly, the relationship of abnormal middle-ear and ET function prior to cleft palate repair, which normalized after the palatoplasty, is borne out in an animal model. Eight monkeys with a surgically induced cleft palate had abnormal ET function. Once the palate was repaired, the ET function normalized (40).

The big question is what happens to the ET function in a child with a cleft palate after the cleft is repaired? Although the muscle sling was repaired, there is not an immediate improvement in ET function. There seems to be improved retrograde function and prograde clearance, but a functional obstruction still exists. Follow-up ET function testing after cleft repair suggests there is still difficulty at equilibrating negative pressures (37). Chronic otorrhea, which is often present in children with ear tube placement prior to their palatoplasty, improves significantly and fairly soon after the repair (41,42). Approximately 70% of children with a cleft palate obtain normal ET function 6 to 10 years after the repair.

The mantra for the treatment of ET dysfunction in a child with a cleft palate has long been the placement of TT "early and often." Increasingly though, there is debate about the appropriate timing of TT placement. At our institution, TTs are placed at the time of CL repair if there has been any history of acute otitis media, any documented physical examination with MEE, or any abnormal tympanometry or audiometry. If the infant has passed the newborn hearing screening examination and has been heretofore free of middle-ear disease, an examination of the ears while under anesthesia is performed. If the ear examination is normal, no TTs are placed. If there is a MEE, TTs are placed at that time. Regardless of the history or examination findings, TTs are placed at the time of the palate repair. After this initial set of TTs are placed either at the time of the palate repair or sometime prior to this, the ears are examined at intervals until the TTs extrude. An assessment is made at that time to determine if the sequelae of the ETD recur after the tube extrusion. Smith et al. reported an average of 3.1 sets of Armstrong tubes and 1.1 sets of T-tubes for a child after palate repair (43).

In addition to having an increased number of sets of TT, children with a cleft palate are more likely to have cholesteatoma. Dominguez determined that the prevalence of cholesteatoma in children with cleft palate was 9.2% compared to 6 per 100,000 for the noncleft population. The patients ranged in age from 6 to 15 years and each had many sets of TT placed. All had a prior retraction pocket (44). This increase in the cholesteatoma risk necessitates careful interval examinations and timely TT placement for any retraction pocket noted.

Airway Issues in the Cleft Palate Population

Airway Obstruction/Obstructive Sleep Apnea

Children who have a cleft palate are at higher risk for upper airway obstruction than their noncleft peers. Children with cleft palate as part of a syndrome such as Apert syndrome or Pierre Robin sequence (PRS) are even more likely to experience airway obstruction. This airway obstruction may be manifested in a variety of circumstances and in a range of severities. At birth, aside from concerns with feeding and swallowing, there may be signs of airway obstruction, particularly if there is any degree of retrognathia. This may be explained anatomically, since the possibility of airway obstruction at multiple levels exists: from nasal obstruction due to a deviated nasal septum to hypopharyngeal obstruction due to collapse of the epiglottis and base of tongue (EBT). Children with PRS are especially prone to this type of hypopharyngeal collapse as a sequela of the retrognathia present in this population. In general, the more severe the retrognathia, the more severe the EBT collapse. The airway obstruction symptom severity in this circumstance often coincides with the severity of the EBT collapse. Mild airway obstruction at birth may prompt only conservative measures such as prone positioning or a nasal or oral airway. A lower threshold to perform airway endoscopy should be employed in children with a syndrome. More severe airway obstruction that does not improve with conservative measures warrants a diagnostic endoscopy in the operating room consisting of at least a flexible nasolaryngoscopy and a direct rigid laryngobronchoscopy (DLB) that serves many purposes. The exact anatomic location of the airway obstruction may be determined. If the severity of the obstruction warrants it, or if multiple levels of obstruction are present, surgical intervention to improve the safety of the airway is indicated. The direct laryngoscopy also allows an assessment as to the ease of orotracheal intubation. If additional intervention is required, the patient may be intubated as part of the endoscopic procedure. The technique for DLB in children is described elsewhere. A DLB in an infant with PRS is more difficult technically because of the retrognathia and the position of the mandible relative to the anteriorly placed larynx.

Children may experience an increase in airway obstruction symptoms at the time of their palatoplasty. This may be due to a decrease in the functional airway space caused by closure of the palate. The tongue is acutely more swollen because of pressure applied by the Dingman retractor during the palatoplasty and closure of the palate decreases the available space that the tongue has previously occupied. Placement of nasal airways prior to the extubation after palatoplasty may alleviate some of the airway obstruction symptoms.

Other circumstances, which may make a child with cleft palate more susceptible to airway obstruction, include children with a syndrome causing generalized hypotonia, children who have undergone another procedure that may partially compromise airway patency (e.g., pharyngeal flap). An assessment of the severity of the airway obstruction with airway endoscopy may be required in this setting. Endoscopy may also be helpful when the severity of the symptoms of either airway obstruction or obstructive sleep apnea described by the caregiver does not correlate with physical examination findings.

One of the manifestations of airway obstruction is obstructive sleep apnea (OSA). OSA is defined as a "disorder of breathing during sleep characterized by prolonged partial upper airway obstruction and/or intermittent complete obstruction that disrupts normal ventilation during sleep and normal sleep patterns" (45). The prevalence of OSA in the general pediatric population is approximately 2% to 3% (46) with 3% to 12% having primary snoring (47). Multiple studies have shown that children with a cleft palate are more likely to have sleep-disordered breathing with prevalence data ranging from 22% to 65% (48). Robison demonstrated a polysomnogram (PSG)-confirmed prevalence of OSA of 8.5%, approximately three times the healthy pediatric prevalence of 2% to 3%. In general, the younger patients were more prone to OSA, with decreasing prevalence as the population aged. One exception was a subset of patients who experienced an increase

in their OSA symptoms after surgical repair of their cleft palate or the performance of a pharyngeal flap for VPI (48). Children with PRS are at significantly higher risk of OSA, particularly with more severe airway obstruction symptoms early in infancy.

As noted, the airway management in infants with a syndrome or with PRS is difficult and has been a topic of much debate. In general, infants with nonsyndromic PRS improve with conservative measures such as prone positioning. They are also more likely to have symptomatic improvement after interventions such as mandibular distraction osteogenesis (MDO) or tongue lip adhesion (TLA). Children with syndromic PRS are more likely to need tracheostomy tube placement and/or gastrostomy tube placement and are more likely to fail other interventions such as MDO or TLA. Regardless of the chosen intervention, if the child with PRS has airway obstruction ± OSA that does not resolve with conservative measures, they should have an airway evaluation. At our institution, this evaluation consists of flexible fiberoptic nasolaryngoscopy to get a dynamic assessment of collapse of EBT, if present, and of laryngeal structure and function. A direct laryngoscopy and bronchoscopy is also performed with a twofold purpose: (a) to assess the ease or difficulty of orotracheal intubation and (b) to assess for other pathology in the distal airway. If the anatomic information gathered during the endoscopy warrants consideration for an MDO or TLA, the patient can be intubated at that time.

Each child with a cleft palate should be carefully monitored for history or examination findings that may suggest airway obstruction or OSA. There should be a low threshold for ordering a PSG with any treatment focused on the specific anatomic level of airway obstruction. If no surgical options exist for the treatment of OSA, a trial of bilevel positive airway pressure (BiPAP) should be considered.

Hoarseness

There have been conflicting data as to a higher prevalence of hoarseness and vocal cord pathology in children with a cleft palate compared to noncleft children. Previous reports indicate rates of dysphonia in the cleft palate population from 12% to 43% (49). There are many hypotheses to explain this possible increase in hoarseness. The most common is laryngeal compensation for abnormal velopharyngeal valving (50). If children with a cleft have any degree of VPI that persists after repair of the palate, the hypernasality that exists with articulation of specific consonants may prompt the utilization of compensatory mechanisms to overcome insufficient air pressure in the oral cavity. Some of these mechanisms include middorsum palatal stops, posterior nasal fricatives, velar fricatives, pharyngeal stops, pharyngeal fricatives, and glottal stops (51). Glottal stops, in particular, have been implicated in vocal cord abnormalities and voice disturbances such as hoarseness (51). Because of this tendency for vocal strain and dysphonia, a careful phonatory history plus a low threshold to administer a voice quality of life survey or perform a flexible nasolaryngoscopy, as indicated, is important. Additional investigation based on these findings may be necessary depending on the examination.

CONCLUSIONS

Providing care to patients with OFC is one of the most gratifying and technically challenging endeavors in surgery. The establishment of multidisciplinary cleft teams has allowed patients to receive truly comprehensive care throughout their infancy, childhood, and adolescence—optimizing aesthetic, speech, and functional outcomes for each patient. Continued clinical and basic science research is necessary in all fields pertaining to cleft care, as this clinical problem is widespread, persistent, and difficult for patients and their families alike.

HIGHLIGHTS

- Cleft lip and palate are the most common congenital malformations in the United States, affecting between 0.2 and 2.3 patients per 1,000 births, depending upon race.
- Isolated cleft palate has a higher association with genetic syndromes; Stickler syndrome and microdeletions of 22q being the most common.
- Repair of the cleft lip deformity in otherwise healthy patients is typically performed at 3 to 6 months of age, while repair of the cleft palate deformity is performed at 9 to 12 months of age.
- Care of the cleft patient should be a multidisciplinary endeavor, focusing on all aspects of the child's growth and development.

104 Congenital Vascular Lesions

Ravindhra G. Elluru

In 1982, a seminal article authored by Mulliken and Glowacki (1) marked a turning point in the history of classifying and managing congenital vascular lesions, or more properly termed vascular anomalies. These authors developed a classification system in which vascular anomalies were designated as either vascular tumors or vascular malformations, based on their clinical appearance, histopathologic features, and biologic behavior (Fig. 104.1). Hemangiomas were identified as benign tumors that undergo a phase of active growth characterized by endothelial proliferation and hypercellularity, followed by gradual tumor regression that occurs over the first decade of life. In contrast, vascular malformations were described as structural congenital anomalies derived from capillaries, veins, lymphatic vessels, arteries, or a combination of these. Unlike vascular tumors, vascular malformations were shown to have normal levels of endothelial turnover and to grow proportionately with the child. In the chapter to follow, readers will be presented with a description of the most common types of vascular anomalies and available treatment modalities.

VASCULAR TUMORS

Infantile Hemangioma

The most commonly occurring vascular tumor is the infantile hemangioma, affecting 1 in 10 white infants in North America, though less commonly seen in children of African or Asian descent (2). These tumors are more common in females (3:1) and in infants with low birth weight (3). They are typically observed at birth or during the first several weeks of life. Lesions generally present cutaneously in the head and neck (60%), but can involve any anatomic site, including the extremities (15%), visceral organs, and brain (3).

Infantile hemangiomas are clinically characterized as superficial, deep, or combined, depending on their anatomic depth. Superficial lesions are typically soft, red, and raised, whereas deep lesions show a spectrum of appearance and consistency, ranging from soft and supple to raised and firmer warm masses with a bluish hue. Combined lesions have both a red epidermal coloration and a subcutaneous mass that is either blue or flesh colored.

Although most tumors present singularly, up to 20% of affected infants have multiple cutaneous lesions. When a patient has six or more cutaneous hemangiomas, there is an increased risk of having visceral hemangiomas, which in turn can give rise to serious or life-threatening conditions such as hepatomegaly, gastrointestinal bleeding, profound hypothyroidism, anemia, or congestive heart failure (4,5).

Hemangiomas of infancy generally follow a predetermined clinical course of active growth (proliferation) and later tumor regression (involution); however, there is wide variation in the rate, duration, and degree of growth and spontaneous tumor regression. Proliferation begins during the first few weeks of life and generally continues for 4 to 10 months, though deep lesions may proliferate until 2 years of age. The proliferative phase is followed by a period of quiescence during which the growth rate of the lesion stabilizes. Involution occurs at 12 to 18 months and can last up to 5 to 6 years. During this time, the color of the lesion fades, becoming grayish or dull purple (Fig. 104.2). Clinical studies show that maximum involution occurs in 50% of children by age 5 and in 90% by age 9 (6).

The cosmetic outcome after involution varies considerably and is generally unpredictable. In many patients, involution results in the restoration of normal skin. In others (20% to 40%), residual changes of the skin such as laxity, discoloration, telangiectasia, fibrofatty masses, or scarring are seen in the affected area. Given this unpredictability, for patients who are not at risk, clinical monitoring, parental education, and ongoing support are preferable to early intervention.

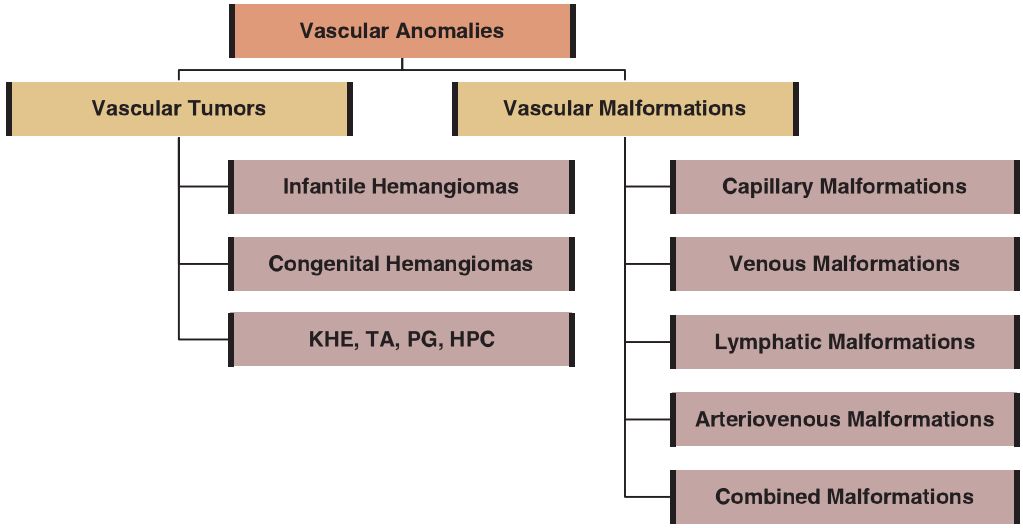

Figure 104.1 A schematic representation of the 1996 ISSVA classification of vascular anomalies. KHE, kaposiform hemangioendothelioma; TA, tufted angioma; PG, pyogenic granuloma; HPC, hemangiopericytoma.

In the growth phase, infantile hemangiomas are composed of proliferating endothelial cells and large numbers of pericytes, mast cells, and fibroblasts (7). As lesions regress, endothelial cell apoptosis increases and the vascular network is slowly replaced by fibrofatty tissue. Over the past two decades, many studies have investigated possible molecular factors that control this tumor life cycle, and considerable progress has been achieved in understanding the etiology of these lesions. To date, however, no single theory can explain key characteristics of hemangiomas, such as the predilection for females, usual occurrence after birth, spontaneous involution, and abnormal tissue architecture.

Proliferating hemangiomas have been shown to have increased expression of type IV collagenase, vascular endothelial growth factor (VEGF), and basic fibroblast growth factor (bFGF) (8). In involuting hemangiomas, the high expression level of bFGF is maintained, whereas the level of expression of VEGF significantly decreases. Gene expression analysis comparing proliferating versus involuting hemangiomas demonstrates that insulin-like growth factor 2 (IGF-2) is highly expressed during proliferation but is significantly decreased during involution (9).

There is sound evidence that hemangiomas of infancy are related to placental endothelial cells. Four markers of hemangioma cells that are coexpressed in placental vessels have been identified: GLUT1 (a glucose transporter enzyme), merosin, Lewis Y antigen, and Fcγ-RIIb (10). GLUT1 is strongly expressed in infantile hemangiomas, placentas, and the blood–brain barrier; however, it is not expressed in normal surrounding vascular endothelium or in vascular malformations nor is it generally expressed in congenital hemangiomas (see discussion below). Because the positive expression of GLUT1 persists throughout all phases of the hemangioma life cycle, this histochemical marker is particularly useful in distinguishing hemangiomas of infancy from other vascular tumors and from vascular malformations.

Congenital Hemangiomas

Congenital hemangiomas are an uncommon variant of infantile hemangiomas. They differ from infantile hemangiomas in clinical behavior, appearance, and histopathology and are occasionally diagnosed *in utero*. Unlike infantile hemangiomas, congenital hemangiomas present at birth as fully grown lesions and do not undergo additional postnatal growth. Congenital hemangiomas fall into distinct subgroups: rapidly involuting congenital hemangiomas (RICHs) and noninvoluting congenital hemangiomas (NICHs) (11). RICHs typically involute by 12 to 14 months of age, leaving a residual patch of thin skin with prominent veins and little, if any, subcutaneous fat. NICHs do not undergo involution. Both tumor types have a predilection for the head or limbs. Both tumor types generally present as solitary violaceous lesions at birth and rarely coexist in a patient with a typical infantile hemangioma. Both are high-flow lesions that can be misdiagnosed as arteriovenous malformations (AVMs). In contrast to infantile hemangiomas, congenital hemangiomas are GLUT1 negative and comprise less than 3% of all hemangiomas seen in infancy (12).

Problematic Head and Neck Hemangiomas

Hemangiomas can occur anywhere in the head and neck region. Hemangiomas can occur singularly on the neck, cheek, nose, ears, forehead, or scalp, or multifocally at several of these sites. The head and neck can also be the site of segmental hemangiomas that occupy an entire developmental subunit (Fig. 104.3).

Figure 104.2 Infantile hemangiomas undergo a process of natural regression. The following series of photographs depict a young girl at **(A)** 2 months, **(B)** 6 months, **(C)** 18 months, and **(D)** 36 months of age. As the child grows older, the hemangioma changes from a bright red color to a grayish red color, and finally to the natural skin color. The mass of the lesion also decreases, leaving little evidence of the hemangioma over time.

Figure 104.3 A series of photographs of children with hemangiomas are presented demonstrating variations in morphology. **A:** Example of a child with an isolated focal hemangioma. **B:** Example of a child with multiple cutaneous hemangiomas. **C:** Example of a child with a facial segmental hemangioma occupying the periorbital, temporal, cheek, and chin areas of the face. Segmental hemangiomas are prone to ulceration as can be seen in this child around the left nasolabial crease.

Phaces

Hemangiomas that present in developmental segments are referred to as "segmental" lesions. These lesions are less common than focal lesions and have a higher risk of being life- or function-threatening and of having associated structural anomalies. Large cervicofacial segmental hemangiomas, particularly those on the forehead, temple, upper cheek, and around the periorbital area can be accompanied by a constellation of anomalies referred to as PHACES association (13). This association is far more common in females. Accompanying anomalies include *p*osterior fossa brain malformations (e.g., Dandy-Walker malformation), *h*emangiomas, *a*rterial abnormalities, *c*ardiac and aortic arch defects (e.g., aneurysms and congenital valvular aortic stenosis), *e*ye abnormalities (e.g., congenital cataract, microphthalmia, and abnormal retinal vessels), and *s*ternal clefts or supraumbilical raphes. More than 50% of patients are affected by neurologic sequelae, including seizures, stroke, developmental delay, and migraines (14).

Segmental hemangiomas are plaque-like in contour, typically undergo an extended proliferative period of 18 months, and unlike most hemangiomas of infancy, they do not completely regress. Furthermore, segmental hemangiomas are at a higher risk of ulceration and residual scarring (13). When there is an index of suspicion for PHACES association, referral should be made for an ophthalmologic and neurologic examination, screening echocardiogram, and possibly a magnetic resonance imaging (MRI) or magnetic resonance angiography (MRA) of the head, neck, and chest. Patients in whom imaging reveals

a central nervous system abnormality should be closely monitored. The frequency of repeated imaging depends on symptom presentation and disease progression.

Hemangiomas in a Beard Distribution

Sixty-five percent of patients with hemangiomas that occur in a beard distribution (i.e., the chin, jawline, and preauricular areas) have associated airway involvement (15), and most airway hemangiomas are localized in the supraglottic or subglottic region. Patients must be closely followed and treatment should be initiated when airway involvement is suspected. Localized lesions are managed with laser ablation, intralesional steroids, surgical resection, or medical therapy (see below). Tracheotomy placement is used only in refractory cases or in cases in which the airway hemangioma is extensive. Hemangiomas that occur in the beard distribution often involve the parotid glands. Parotid gland hemangiomas typically occupy the entire gland and adjacent parapharyngeal space. They grow rapidly, causing extrinsic compression of the upper pharyngeal airway. These lesions frequently have a prolonged proliferative phase (12 to 16 months) and may require systemic therapy if the airway is compromised (16). Children with extensive hemangioma of the parotid region and pharyngeal area often have chronic recurrent otitis media, likely secondary to extrinsic compression of the eustachian tube.

Periocular Hemangiomas

Periocular hemangiomas can involve the upper lid, lower lid, and/or the retrobulbar space (Fig. 104.4). Pressure from the hemangioma on the globe may lead to astigmatism and amblyopia. Early ophthalmologic evaluation and treatment is indicated for all cases of periocular hemangiomas to avoid deprivation amblyopia, which can occur with as little as 1 week of deprivation during key developmental periods. Treatment options for vision-obstructing periocular hemangiomas include either medical therapy or surgical excision. Children older than age 1 who have gone untreated have rates of deprivation amblyopia as high as 75%.

Figure 104.4 An axial cut through the orbit of a child with a right pre- and postseptal orbital hemangioma.

Nose, Lip, and Ear Hemangiomas

Hemangiomas involving the nose occur in close to 16% of facial hemangiomas (17). Proliferation of lesions on the nasal tip often distort the anatomy of the nose, causing misalignment of the nasal cartilages and mild to severe nasal volume increase. Management approaches must consider the depth, location, rate of involution, and functional and cosmetic disturbance caused by the lesion. A multimodal approach combining serial observation, intralesional steroid injection, systemic steroid therapy, pulsed-dye laser (PDL) treatment, and surgical intervention is generally used (18). In view of possible complications such as severe cutaneous infiltration, the consequences on nasal growth, and the psychological impact of nasal distortion, surgical excision before school age is currently recommended. Various surgical techniques have been reported (19).

Lesions of the pinna of the ear can deform normal anatomic structures and result in ulceration with focal destruction of the auricle. Lesions obstructing the auditory canal can cause temporary conductive hearing loss. Lip lesions frequently involute slowly, sometimes leaving residual skin changes. Additionally, lip ulcerations can result in feeding difficulties, secondary infection, and significant scarring.

Subglottic Hemangiomas

Hemangiomas can occur anywhere within the tracheobronchial tree; however, they are most commonly seen in the subglottis (Fig. 104.5). As mentioned above, there is a close association of hemangiomas in a beard distribution with airway hemangiomas. However, airway hemangiomas can occur without associated cutaneous hemangiomas. In fact, only 50% of patients with airway hemangiomas have cutaneous hemangiomas (20). Presentation usually occurs within the first 6 months of life, and the earlier the presentation, the greater the likelihood that patients will require surgical intervention. Symptoms typically include progressive stridor and retractions. The diagnosis is made on rigid bronchoscopy, and though radiologic evaluation (MRI with contrast enhancement) is indicated, it rarely demonstrates extension of the lesion beyond the confines of the subglottis. Lesions are typically asymmetric and usually covered by a normal smooth mucosa.

Open surgical excision is an option in large focal hemangiomas of the subglottis and is accomplished through a vertical tracheotomy extending through the cricoid ring. Typically, a thyroid alar graft is needed to augment the concomitant narrow subglottis (20). Although many other treatment modalities (systemic steroids, intralesional steroids, prolonged intubation, CO_2 [carbon dioxide] and KTP [potassium–titanyl–phosphate] laser ablation, and microdebrider resection) have been used, these modalities carry a significant risk of inducing an acquired or congenital subglottic stenosis (20). Medical management as discussed below is also an option in selected cases.

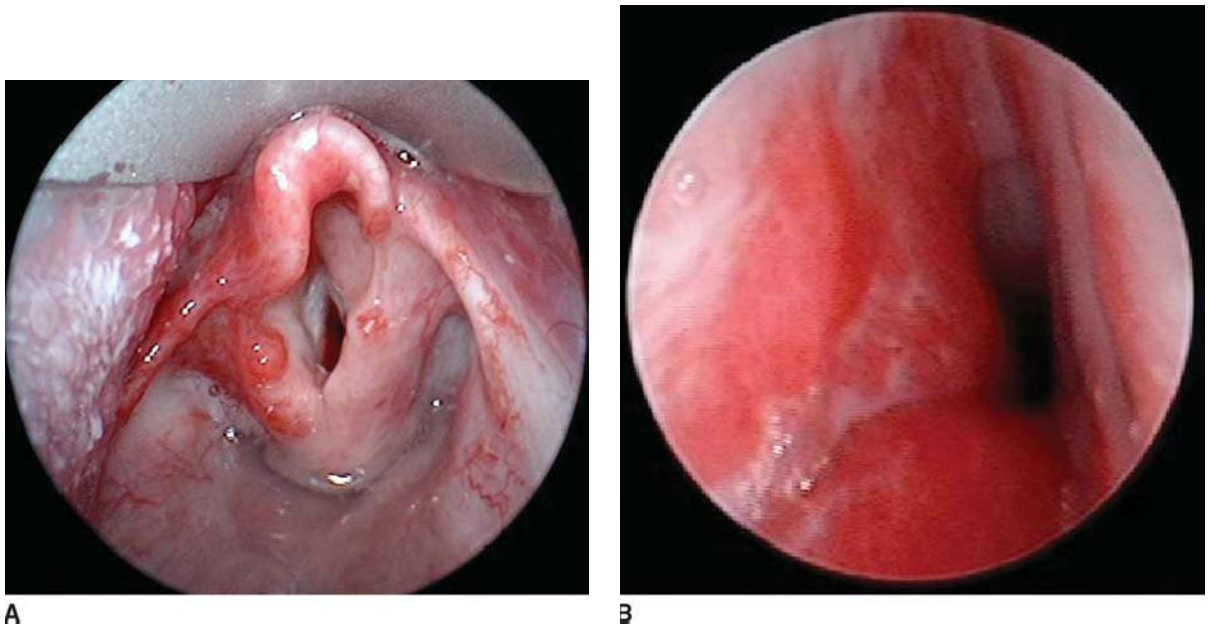

Figure 104.5 Endoscopic photographs of **(A)** a child with flat supraglottic hemangiomas occupying the left epiglottis and aryepiglottic fold and **(B)** a child with a large left subglottic hemangioma that severely narrows the subglottic lumen.

KASABACH-MERRITT PHENOMENON

Kasabach-Merritt phenomenon is a rare, life-threatening condition associated with two specific subtypes of vascular tumors, tufted angioma or kaposiform hemangioendothelioma. Kasabach-Merritt phenomenon is included in this section only to highlight the fact that it is not associated with infantile hemangiomas, as sometimes construed. In Kasabach-Merritt phenomenon, the tumor traps and destroys platelets. In addition to platelet trapping, there are also other associated coagulopathies. As the tumor grows, it causes more platelet trapping. No single treatment approach is effective and unfortunately, responses to various treatments are inconsistent. Initially, corticosteroids are given at varying doses. If this approach is not effective, chemotherapy with vincristine is started. If this regimen is not effective, other drugs such as interferon, Cytoxan, and Amicar are used. If the tumor does not respond to drug therapy, embolization, surgical removal, or both may be necessary. Blood products such as platelets and packed red blood cells are administered only if absolutely necessary. The lesion may take many years to decrease in size. Improvement in platelet counts initially occurs with a decrease in the size of the lesion.

DIAGNOSTIC EVALUATION OF INFANTILE HEMANGIOMAS

The diagnosis of infantile hemangiomas is generally established on the basis of clinical presentation, history, and physical examination. In patients with complex lesions that require surgical intervention, additional investigations can be helpful in determining the extent of involvement. Ultrasound (US) with color flow Doppler can be extremely useful in differentiating hemangiomas from vascular malformations that may have a similar appearance. On US, an infantile hemangioma appears hypoechoic, well defined, and heterogeneous in texture, with small cystic and sinusoidal spaces. In most proliferating hemangiomas, a characteristic fast-flow pattern is visualized by Doppler US. Typically, a quick upstroke and gradual down slope is seen (Fig. 104.6).

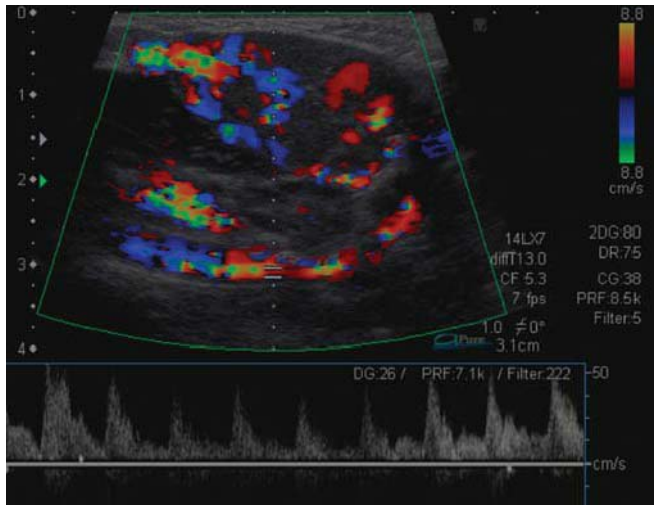

Figure 104.6 Color ultrasound Doppler image of an infantile hemangioma. Infantile hemangiomas are composed of small blood vessels conducting blood at high flow rates **(top panel)**. Doppler demonstrates that the blood flow in these small blood vessels is pulsatile, characterized by a rapid upstroke and a gradual down stroke in flow rates **(bottom panel)**.

TABLE 104.1 MRI CHARACTERISTICS OF VASCULAR ANOMALIES

Anomaly Type	T1-Weighted	T2-Weighted	Contrast	Gradient
Hemangioma	Soft tissue mass, isointense or hypointense, flow voids	Lobulated soft tissue mass, increased signal, flow voids	Uniform intense enhancement	High-flow vessels within and around soft tissue mass
Venous malformation	Isointense to muscle, possible high-signal thrombi	Septated soft tissue mass, high signal, signal voids (phleboliths)	Diffuse or inhomogeneous enhancement	No high-flow vessels
Lymphatic malformation	Septated soft tissue mass, low signal	Soft tissue mass, high signal, fluid levels	Rim enhancement or no enhancement	No high-flow vessels
Arteriovenous malformation	Soft tissue thickening, flow voids	Variable increased flow voids	Diffuse enhancement	High-flow vessels throughout abnormal tissue

Dubois J, Garel L. Imaging and therapeutic approach of hemangiomas and vascular malformations in the pediatric age group. *Pediatr Radiol* 1999;29(12):879–893.

MRI and computed tomography (CT) scans can delineate the extent and involvement of the hemangioma and can also be helpful in distinguishing hemangiomas from other malformations (21) (Table 104.1). In the proliferative phase, a hemangioma appears as a well-circumscribed tumor with homogeneous parenchymatous density and intense enhancement. In the involutive phase, it appears heterogeneous, with distinct lobular architecture and large draining veins in the center and the periphery. Through rarely used for the diagnosis of vascular anomalies, conventional angiography can provide information about the size of lesions and feeding vessels and can also distinguish between hemangiomas and other vascular malformations. Biopsy is indicated only when the diagnosis is uncertain or when the possibility of malignancy must be ruled out.

Treatment of Infantile Hemangiomas

Most uncomplicated focal hemangiomas involute spontaneously and do not require intervention. Nevertheless, rapidly proliferating lesions are sometimes problematic and can cause a wide array of complications, including ulceration, infection, hemorrhage, necrosis, airway obstruction, loss of vision, and cardiac failure. To ensure timely intervention should any of these complications occur, patients should be closely monitored during the proliferative phase. Optimally, management strategies for complex lesions should be planned by a multidisciplinary team of clinicians with expertise in treating vascular anomalies. Management decisions should consider the size and location of the lesion, the presence of complications at diagnosis, the age of the patient, and the rate of tumor growth. Large segmental hemangiomas and life- or function-threatening hemangiomas are likely to require immediate treatment. Immediate treatment is also essential in the presence of ulceration or secondary infection. Serious aesthetic concerns such as the possibility of permanent disfigurement or scarring warrant early intervention.

These patients almost always require multimodal therapy. Major therapies currently include pharmacotherapy, chemotherapy, laser therapy, and surgical excision. Recently, the dramatic effect of oral propranolol has been reported in several small case series (22–24), and prospective studies are underway at several major centers. Although research regarding propranolol is in its infancy, this medication has replaced steroids as the first line in medical management. Propranolol is discussed further below.

Ulceration is the most common complication of hemangiomas, often occurring in lesions involving the nose, lips, and periorbital region (25). Most ulcers develop during a phase of rapid growth. They are often painful and can lead to infection, anemia, scarring, and disfigurement. Treatment should focus on decreasing pain, preventing secondary infections, and promoting reepithelialization. Painful ulcerations may require oral medications such as acetaminophen or acetaminophen with codeine. Superficial ulcerations generally respond to supportive therapy such as gentle cleansing and the daily application of a topical antibiotic. Dressings that cover the ulceration such as DuoDERM or Mepilex can provide pain relief and promote healing. When an associated cellulitis occurs, oral systemic antibiotics are given. Ulcerations on localized cervicofacial lesions are amenable to surgical resection, which generally results in excellent cosmetic outcomes. When resection is not feasible or desirable, PDL is used to promote reepithelialization and decrease pain. This approach is particularly helpful in anatomic areas that are not amenable to resection, such as extensive facial lesions. Products such as imiquimod, which stimulates endogenous interferon production, and becaplermin gel, which appears to accelerate reepithelialization, have been used for treating refractory ulcerated hemangiomas but require further study.

Until recently, corticosteroids have remained the first line of therapy for the treatment of complicated hemangiomas (26). Currently, the two indications for the use of corticosteroids in the treatment of infantile hemangiomas are for

those patients who fail propranolol treatment and for intralesional injection in small focal hemangiomas (27). Local injection is especially effective in the periorbital region, nasal tip, and subglottic region. Some surgeons and ophthalmologists recommend using general anesthesia, whereas others perform the procedure on an outpatient basis using a topical anesthetic. A long-acting steroid (e.g., triamcinolone acetonide) and a short-acting steroid (e.g., betamethasone acetate) can be combined in a total volume that generally does not exceed 2.5 mL. The dose and volume are individualized according to the size of the lesion. A 25-gauge needle is used and injections are made directly into the hemangioma in different directions through the same needle hole. Following this, direct pressure is applied for 2 to 10 minutes to stop bleeding. In subglottic lesions, it is important to avoid direct injection of the cricoid plate, as cartilage resorption may occur. Although this approach is associated with a 70% to 90% response rate in periorbital hemangiomas, a known complication is the risk of retinal artery embolization and thrombosis, with resulting blindness (28). To lessen this risk, fundoscopic retinal examination should be performed as the lesion is slowly injected so to recognize early signs of retinal arterial flow interruption. Adrenal suppression and failure to thrive have also been reported following local injection for periocular hemangioma (27).

Propranolol, a nonselective beta-blocker, has recently been introduced as a novel modality for the treatment of proliferating hemangiomas. The dramatic effect of propranolol therapy on hemangiomas was first described in 2008 by Leaute-Labreze et al. (22). These authors serendipitously discovered that propranolol induced early regression of infantile hemangiomas during their proliferative phase. Their reported findings in a small series of infants sparked the enthusiasm of clinicians eager to identify appropriate uses for propranolol. Buckmiller et al. (24) reported the successful management of tracheal hemangiomas in a young patient with otherwise treatment-resistant airway lesions. Within 6 weeks of beginning oral propranolol (2 mg/kg/day), airway compromise was eliminated and the patient had complete resolution of endoscopically visible disease. No side effects occurred. Denoyelle et al. (23) reported the successful management of two infants with subglottic hemangiomas that were resistant to established medical treatments. Both patients' subglottic hemangiomas responded dramatically to propranolol, and no side effects were noted. The mechanisms of action are speculative, but may involve the downregulation of angiogenic factors and upregulation of apoptosis. In summary, early research illustrates that propranolol may be a safe and effective therapeutic strategy for both cutaneous and airway lesions. There is controversy as to the diagnostic testing needed prior to drug administration and the appropriate venue (inpatient or outpatient) for drug. Table 104.2 depicts an inpatient and outpatient algorithm developed

TABLE 104.2 PROTOCOL TO INITIATE PROPRANOLOL THERAPY

Inpatient propranolol algorithm

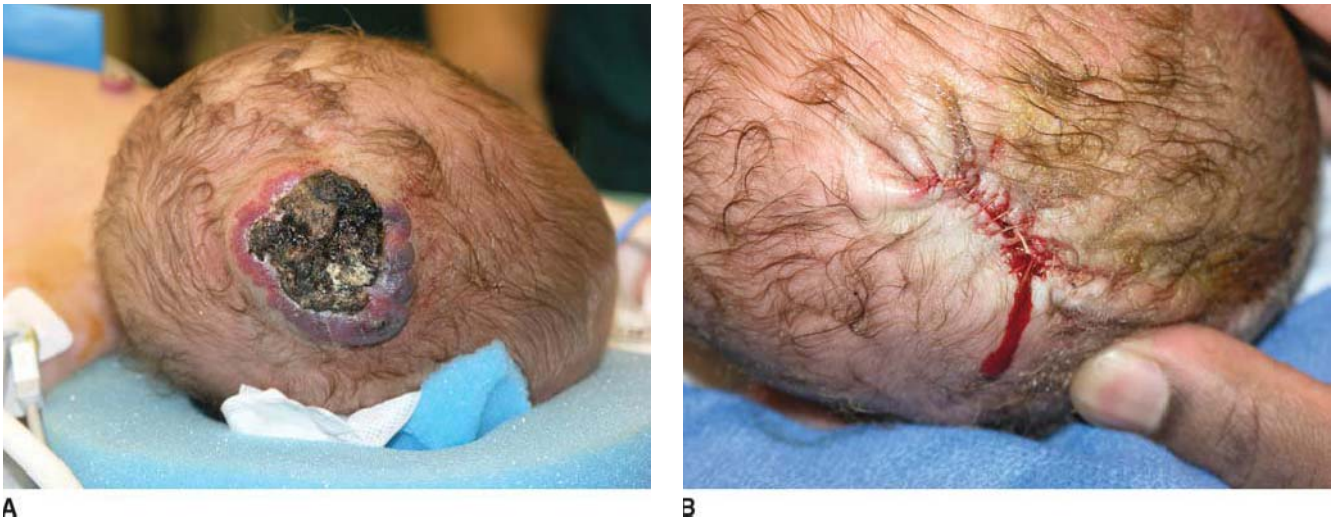
- Preadmission diagnostic testing—echocardiogram to rule out congenital anomalies in patients with a history of murmurs, failure to thrive, or other significant medical comorbidities; EKG to rule out cardiac arrhythmia
- Admit to telemetry unit with continuous heart rate and blood pressure monitoring
- Initiate propranolol at 0.5 mg/kg PO BID for 2 doses; increase to 1 mg/kg PO BID for 2 doses; finally increase to 2 mg/kg PO BID
- Propranolol is increased in this manner as long as the patient exhibits no adverse response to the administration of the medication
- Check blood glucose 2 h after each dose of propranolol
- Check EKG 24 h after initiation of propranolol
- Discharge home after second dose of propranolol at 2 mg/kg with contact information if questions or problems arise
- Parents are instructed to maintain a strict feeding regimen. If the child is <6 mo of age, feedings should be every 2–4 h. Older children can be spaced to feedings every 6–8 h
- Parents instructed to hold medication if the child becomes ill and/or has decreased PO intake

Outpatient propranolol algorithm

- Diagnostic testing—same as for inpatient algorithm
- Monitor on telemetry unit for 6 h with continuous blood pressure and heart rate monitoring
- Initiate propranolol at 0.5 mg/kg
- Check blood glucose 2 h after each dose of propranolol
- Discharge instructions as for inpatient algorithm with contact information if questions or problems arise
- Continue propranolol at 0.5 mg/kg PO BID or 1 wk
- Return to hospital for 6 h admission on telemetry unit during which propranolol is increased to 1 mg/kg. An EKG is obtained prior to increasing the dose and blood glucose is checked 2 h after dose. Discharge home at this dose for a week with discharge instructions as previous
- Return to hospital for 6-h admission during which propranolol is increased to 2 mg/kg. Blood glucose is again checked 2 h after dose. Patient is discharged home with discharge instructions as previous with follow-up in 4 wk

by our vascular anomalies team. In general, we advocate inpatient protocol for infants less than 2 years of age and children with comorbidities. The parents of all other children are given the choice of inpatient or outpatient treatment. Side effects that have been reported to date include hypoglycemic seizures and sleep disturbances.

Lasers have a limited role in the treatment of hemangiomas. The PDL is often used at the end of the involution phase to reduce any residual vascular markings. PDLs are also used as mentioned above to promote wound healing, reepithelialization, and pain control for ulcerated hemangiomas that are refractory to medical management. The CO_2 and Nd:YAG (neodymium-doped yttrium aluminum garnet) lasers have been used to ablate airway hemangiomas, though overaggressive use of these lasers can cause scar deposition and subglottic stenosis.



The indications for the surgical excision of hemangiomas are in evolution, especially with given the natural regression of these lesions and the efficacy of medical management. Nonetheless, there are several clinical situations in which surgical excision is an attractive treatment option (Table 104.3). Large hemangiomas that are likely to leave large amounts of fibrofatty residuum or excess skin are often good candidates for surgical excision. Ulcerative hemangiomas that fail medical management and can be excised completely are another candidate for surgical excision (Fig. 104.7). Periorbital hemangiomas and airway hemangiomas that are causing significant symptomatology and are unlikely to respond quickly or do not respond to medical management are often best treated by surgical excision. Finally, hemangiomas that are not completely resolved by school age and cause psychosocial distress can also be treated with surgical excision. The timing of surgery remains a controversial subject, particularly in regard to early surgery on hemangiomas that are disfiguring and in which the ultimate results of spontaneous involution are difficult to predict. In summary, surgical intervention should be considered when surgery is thought to provide a better overall outcome to the patient than natural regression or medical management.

TABLE 104.3 RELATIVE INDICATIONS FOR SURGICAL MANAGEMENT OF HEMANGIOMAS

- Noninvoluting congenital hemangioma
- Ulcerative hemangioma that will likely leave a large scar
- A hemangioma that is causing significant functional compromise or symptomology and is not responding expeditiously to medical management. Examples of functional compromise include obstruction of visual axis with changes in vision or airway obstruction.
- A hemangioma that has a pedunculated appearance, and therefore will likely not involute completely.
- A hemangioma that causes significant psychosocial or appearance issues to the patient as he/she enters school can be removed with a satisfactory cosmetic outcome.

VASCULAR MALFORMATIONS

Vascular malformations are the second major category of vascular anomalies (Fig. 104.1). In contrast to vascular tumors, vascular malformations are present at birth and grow commensurately with size of the child. Although the molecular mechanisms underlying the formation of these lesions remain unclear, they are known to result from abnormal development and morphogenesis. Histologic examination of vascular malformations shows no evidence of cellular proliferation but rather progressive dilation of abnormal channels. Vascular malformations are designated according to the predominant channel type present. They are classified as capillary, venous, lymphatic, arterial, or

A B

Figure 104.7 Photographs of a patient with a large ulcerative scalp hemangioma **(A)** that was surgically excised **(B)**.

combined malformations. Malformations with an arterial component are rheologically fast flow, whereas capillary, lymphatic, and venous malformations are slow flow in nature. The morbidity of vascular malformations varies greatly both within and among the clinical subgroups cited above.

Diagnostic Modalities

Accurate and expeditious diagnosis is essential to the proper treatment of vascular malformations. A diagnosis is arrived upon only after a thorough and complete history and physical exam. Key parts of the history include the age at which parents initially noticed the lesion; overall rate of growth of the lesion as well as recent changes in the size of the lesion; and acute changes in the size of the lesion concordant with upper respiratory tract infections, trauma, hormonal changes, body position, Valsalva maneuver, or high cardiac output states. In addition to the above history, a complete review of systems is essential. Fundamental aspects of the physical exam include the extent and color of the lesion, the three-dimensional morphology of the lesion, temperature, presence of vascular marking, compressibility of the lesion, and whether the lesion is pulsatile.

Radiologic imaging is frequently the next step in the diagnostic algorithm, which is used not only to validate the clinical diagnosis but also to determine the extent of the lesion. Imaging modalities used include US, MRI, and, infrequently, arteriograms. Each subclass of vascular malformation has classic radiologic findings that are helpful in diagnosis (Table 104.1). The success of using radiologic imaging as a tool in the diagnosis of vascular malformations depends on the expertise of the radiologist. In most institutions, the radiologist is a key member of the multidisciplinary team that delivers care to children with vascular anomalies.

Capillary Malformations

Capillary malformations are the most commonly occurring subgroup of vascular malformations. The two most common types of capillary malformations are salmon patches (nevus simplex) and port-wine stains (nevus flammeus) (Fig. 104.8). This malformation consists of a superficial collection of ectatic vessels that is located in the papillary and superficial reticular dermis, with a mean depth of 0.46 mm (29). Salmon patches are extremely common and manifest as macular capillary stains, colloquially referred to as "angel kisses" or "stork bites." They generally appear as pink macules on the forehead, eyelids, nose, and nuchal region and characteristically fade or disappear during childhood. Port-wine stains also present at birth as flat, light pink, macular lesions. However, in contrast to "angel kisses" or "stork bites," port-wine stains become raised, nodular, or darken to a deep red and persist throughout life. Port-wine stains occur in 0.3% of newborns and frequently appear within the distribution of the trigeminal nerve (30,31).

The majority of isolated port-wine stains occur sporadically, though an autosomal dominant inheritance pattern has been reported in some families. Port-wine stains may occur in conjunction with other vascular anomalies or congenital malformations. For example, in Wyburn-Mason syndrome, port-wine facial stains are associated with a unilateral AVM of the retina and intracranial optic pathway (30,31). When port-wine stains appear in the trigeminal nerve distribution, there may be associated structural and vascular abnormalities of the face and leptomeninges (Sturge-Weber syndrome) (32) (Fig. 104.8). Glaucoma occurs in approximately 10% of patients with facial port-wine stains and can occur without leptomeningeal involvement. For the above reasons, children with craniofacial involvement should undergo an MRI or CT scan to rule out central nervous system pathology.

A B

Figure 104.8 **A:** Photographs of a salmon patch on the posterior neck of a patient. **B:** Photograph of a port-wine stain covering the upper right half of the face.

Sturge-Weber syndrome deserves additional attention, given its unique clinical manifestations. Sturge-Weber syndrome typically presents with a facial port-wine stain in the ophthalmic distribution of the trigeminal nerve, glaucoma and vascular eye abnormalities, and an ipsilateral intracranial vascular malformation. Children with Sturge-Weber syndrome often develop progressive neurologic problems, including seizures, migraines, stroke-like episodes, learning difficulties or mental retardation, visual field impairment, or hemiparesis. Furthermore, overgrowth of the craniofacial skeleton can sometimes be noted on the side of the lesion, causing most notably a cross-bite deformity. The specific genetic and environmental factors that result in the disorder are unknown, but the localized abnormalities of blood vessel development and function affecting the facial skin, eye, and brain suggest that a developmental disruption occurs during the first trimester of pregnancy (32).

Treatment with PDL is often used to mitigate the red coloration of port-wine stains and prevent the progression to more darkly colored and raised lesions. Based on the theory of selective photothermolysis (33), PDL is able to preserve the epidermis by allowing hemoglobin to be more precisely targeted within lesions, resulting in less injury to adjacent nontargeted tissue. In capillary lesions that have thickened and become darker with age, the Nd:YAG laser has been used successfully, though patients are often left with some residual scarring. Other options, though of limited use, include surgical debulking of hypertrophied lip and eyelid tissue and skin grafting of facial aesthetic units (30,31). Medical management usually takes top priority and consists of ameliorating associated health problems such as glaucoma and seizures.

VENOUS MALFORMATIONS

Congenital venous malformations consist of either localized or diffuse ectatic veins with abnormal collections of irregular venous channels having flat, mitotically inactive endothelia and scant mural smooth muscle. These lesions may be superficial (i.e., intradermal or subcutaneous) or deep (i.e., intramuscular or intraosseous) (Fig. 104.9). For the most part, they are asymptomatic. Superficial venous malformations have a bluish compressible mass with no palpable thrill or audible bruit. These lesions often enlarge when the lesion is in a dependent position, with Valsalva maneuver, or high cardiac output states. Phleboliths can be seen on x-ray and are pathognomonic for venous malformations. Doppler echocardiography, MRI or MRA, and direct puncture phlebography may be required to confirm the diagnosis and assess the extent of the lesion. When malformations are extensive, a blood coagulation profile should be performed. Patients should also be screened for genetic polymorphisms associated with an increased risk of aberrant clotting (i.e., factor V Leiden, plasminogen activator inhibitors [PAIs], and methylenetetrahydrofolate reductase [MTHFR]). Since patients with extensive venous malformations are at risk for a pulmonary embolus following surgery, they require antithromboembolic prophylactic treatment (26).

Figure 104.9 Photograph of a young boy with an extensive venous malformation of the right check and lower lip.

Treatment depends upon the location, associated symptoms, and extent of the venous malformation. Phleboliths within the malformation often cause pain. Symptoms caused by phleboliths can be treated medically with aspirin, nonsteroidal antiinflammatory drugs, or low molecular weight heparin. When a lesion is localized and accessible, surgical excision results in excellent outcomes. More extensive lesions are often not amenable to resection or only partially resectable. To preserve function when vital structures are involved, a series of sclerotherapy procedures with one of a variety of sclerosing agents (see section below on Lymphatic Malformations) is often performed (34). Superficial lesions or the superficial component of deep lesions can be treated with the Nd:YAG laser (35). Recurrent painful intramuscular or intraarticular bleeding or thrombosis and phlebolith formation can be ongoing problems.

LYMPHATIC MALFORMATIONS

Lymphatic malformations are benign vascular lesions that arise from embryologic disturbances in the development of the lymphatic system. They encompass a wide spectrum of abnormalities, including cystic lymphatic lesions (formerly referred to as "lymphangiomas"), lymphangiectasis, and lymphedema. Given that lymphangiectasis and lymphedema usually involve sites other than the head and neck, these topics will not be further discussed in this chapter.

Cystic lymphatic malformations can be seen in any anatomic region but are more commonly seen in rich lymphatic areas, such as the head and neck (45% to 52%), axilla, mediastinum, groin, and retroperitoneum. These malformations are thought to be the result of maldevelopment of the embryonic lymphatics or lymphatic jugular sacs, with failure of these structures to connect or drain into the venous system. In some patients, a venous malformation can be seen in association with a cystic lymphatic lesion. There are

three morphologic types of cystic lymphatic lesions: microcystic, macrocystic, and combined. Microcystic malformations present as clear, tiny vesicles that permeate the subcutaneous tissue and muscles. Microcystic lesions are commonly found above the level of the mylohyoid muscle and involve the oral cavity, oropharynx, tongue, parotid gland, submandibular gland, and preepiglottic space (Fig. 104.10). These vesicles are often firm and may give the impression of a brawny edema. Macrocystic lesions are large, compressible or noncompressible, smooth, translucent masses under normal or bluish skin. Most macrocystic lesions are multilocular structures consisting of numerous cysts that vary in size. Macrocystic lesions are often located below the level of the mylohyoid muscle and involve the anterior and posterior cervical triangles (30,31).

Histologically, cystic lymphatic malformations are composed of vascular spaces filled with eosinophilic and protein-rich fluid. A single layer of flattened endothelium lines the walls of lymphatic channels. The fibrovascular vessel walls are of variable thickness, with both abnormally formed striated and smooth muscle components. Collections of lymphocytes are common throughout the contained connective tissue. Hemorrhage within the cystic spaces is common, indicating recent trauma or spontaneous intralesional bleeding.

Large cystic lymphatic lesions can be diagnosed *in utero* by US as early as the beginning of the second trimester, but lesions are more commonly noted at birth; the vast majority are evident by age 2. Although large cervical or axillary lesions identified in the perinatal period have been referred to as "cystic hygromas," this term is incorrect, as it does not encompass the morphology and distribution of most cystic malformations. The prenatal diagnosis of anterior and posterior cervical lymphatic malformations has significant clinical implications. They may be associated with airway obstruction, and prenatal diagnosis can influence the mode, timing, and place of delivery. Specifically, the prenatal diagnosis of large cervicofacial lymphatic malformations can signal the need to prepare for possible interventions to control a precarious airway in the delivery room. These patients may require the presence of a skilled surgical team capable of performing an EXIT (*ex utero*

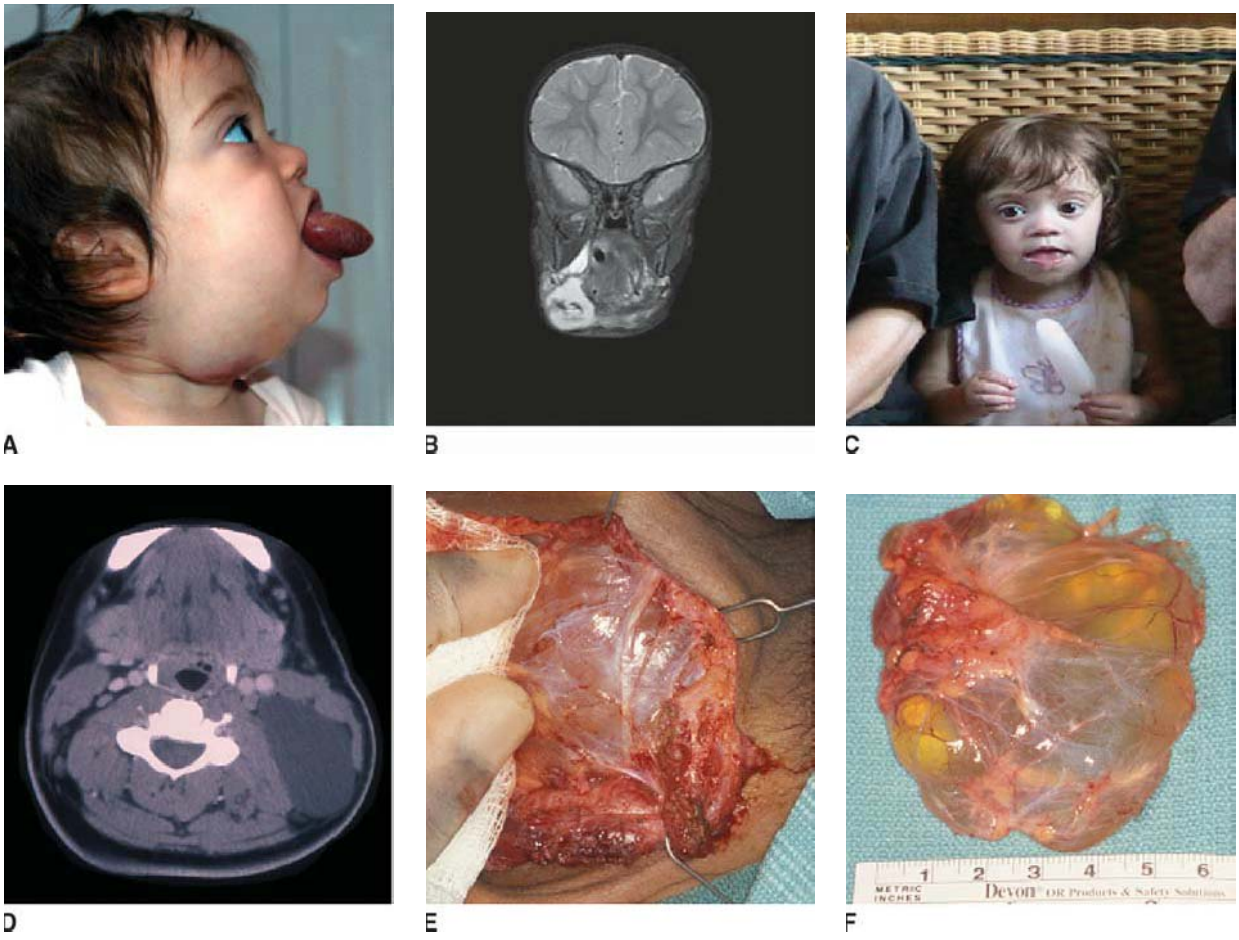


Figure 104.10 **A:** Combined microcystic and macrocystic malformation of the tongue, floor of mouth, and anterior neck. **B:** MRI with gadolinium of the same patient. **C:** Postoperative picture after excision of cervical disease and tongue reduction. **D:** CT scan of neck demonstrating macrocystic malformation of the lateral neck. **E** and **F:** intraoperative pictures demonstrating the appearance of a macrocystic lymphatic malformation.

intrapartum treatment) procedure as well as a spectrum of other techniques, including fiberoptic and rigid endoscopy and direct surgical airway access. Posterior cervical lesions that arise in the perinatal period have been associated with Turner syndrome, as well as other syndromes and congenital anomalies. In this particular situation, there is an associated high prenatal mortality rate secondary to hydrops and diffuse lymphedema. Therefore, amniocentesis with chromosomal analysis should be performed and genetic and family counseling provided (36).

Postnatally, most cases are readily diagnosed by physical examination. Transillumination can be helpful in differentiating some cystic lesions from solid masses. All patients with cervical cystic lesions should have a chest x-ray to determine the presence or absence of mediastinal involvement. Although US is helpful in confirming the diagnosis in superficial lesions, it is less valuable for showing extension into deep structures of the neck, thoracic cavity, and retroperitoneum. CT or MRI can clearly demonstrate the anatomic extent of cystic lesions and their relationship to soft tissues, muscle, and vascular structures.

Cystic lymphatic malformations are associated with numerous complications. Cutaneous involvement can be associated with spontaneous lymphatic leakage from pathologic vesicles. Bacteria can readily enter via these vesicles and quickly spread through tissues affected by the lymphatic lesion. The result is acute cellulitis and/or recurrent cellulitis, which in turn can lead to cosmetic disfigurement and life-threatening sepsis. Given the morbidity of such infections, aggressive antimicrobial therapy is mandatory (30,31).

Another very serious complication caused by large lymphatic malformations of the head and neck is respiratory obstruction of the larynx and trachea. Management is extremely difficult and requires staged operative procedures, speech and physical therapy, and long-term follow-up, preferably by a multidisciplinary team. Less commonly, dysphagia is caused by the involvement of the hypopharynx and the esophagus. Other complications include localized hemorrhage into cysts and nerve compressions that can cause paresthesias and pain. Chylothorax and chylopericardium have been reported as rare complications of cervicomediastinal lesions.

Treatment depends upon the clinical presentation, the size of the lesion, the anatomic location, and the complications. Although complete excision of the lesion is the treatment of choice, this is sometimes impossible. Whereas small lesions are generally amenable to excision with excellent results, large lesions that involve deep structures of the neck, tongue, and mediastinum entail the risk of multiple complications, including fistula formation, infection, damage to vascular structures, damage to nerves, and cosmetic deformity. Past reported mortality rates of such complex lesions vary from 2% to 6%. Persistent disease manifests in about 30% of patients who have undergone gross excisions. It is important to remember that in the absence of symptomatology, it is reasonable and appropriate to manage lymphatic lesions nonoperatively. Surgical excision cannot be done without scarring, and undesirable scars can develop after excision of large intradermal and subcutaneous microcystic and vesicular lymphatic lesions. In some patients with extensive microcystic disease, lymphatic vesicles may become apparent, in or around the scar, years after excision (37).

Sclerotherapy is frequently used as an alternative to surgery for patients with macrocystic disease, and although it is not generally curative, approximately 40% of patients will have amelioration of their symptoms (30,31). A number of sclerosing agents have been used, including ethanol, bleomycin, OK-432 (known also as Picibanil), doxycycline, and sodium tetradecyl sulfate. In the United States, medical grade (90% to 95%) ethanol is the most commonly used agent because of its efficacy and widespread availability (38). Lymphatic cysts are aspirated under US guidance and ethanol is injected into the cyst, with a dose ranging from 1 to 2 mL/kg. When lesions are large, an intralesional closed suction drain is placed for 24 hours in order to aspirate ongoing fluid drainage. Owing to concerns about pulmonary toxicity, bleomycin sulfate is not commonly used in North America (39). Injection of 0.3 to 0.6 mg/kg is given through a 21-gauge needle into the cavity of the malformation after aspiration of lymphatic fluid. Using this approach, total doses remain relatively low and do not approach doses associated with the development of pulmonary fibrosis. OK-432 is derived from a lyophilized mixture of group A *Streptococcus pyogenes* incubated with benzylpenicillin. It is not yet approved in the United States, though its use appears to show promise for macrocystic lesions. It is thought that this compound works by increasing endothelial permeability and accelerating lymph drainage from lymphatic spaces. A solution of OK-432 is prepared by dissolving 0.1 mg of OK-432 in 10 mL of normal saline. After aspirating as much cyst fluid as possible, the solution is injected to a maximal total dose of 0.2 mg of OK-432 in one treatment session. When the initial response to any sclerosant is unsatisfactory, treatment is repeated at 6-week to 3-month intervals.

Swelling of the malformation is a dangerous side effect of sclerotherapy. It can cause airway compromise, especially when the lesion is located in the cervical area and mediastinum. The procedure is thus usually performed in the hospital under general anesthesia, and patients are subsequently observed for 24 hours. Common side effects include fever for 2 to 4 days and local inflammatory reaction with tenderness, erythema, or swelling of the lesions, which lasts for 1 to 3 weeks. When treatment is unsuccessful or yields only a partial response, surgery may be required.

ARTERIOVENOUS MALFORMATIONS

AVMs are congenital vascular lesions associated with a variable degree of arteriovenous shunting (30,31). Some of these lesions are thought to originate from arteriovenous

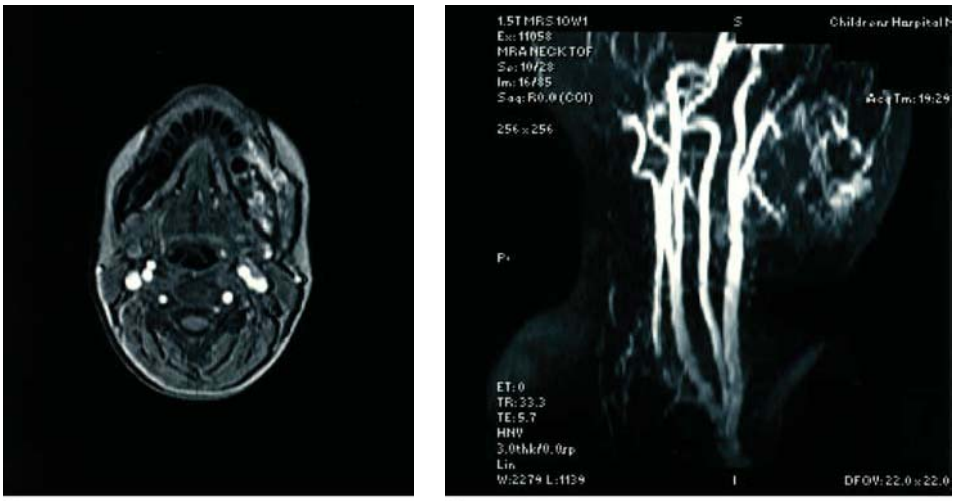

Figure 104.11 **A:** MRI and **(B)** MRA of the neck demonstrating an AVM of the left mandible.

channels that have failed to regress during development. These high-flow communications between arteries and veins are among the most dangerous vascular anomalies. They are always multiple and vary in diameter from several millimeters to the size of the normal precapillary anastomosis. The length of the channels between the arteries and the veins can vary from millimeters to centimeters, and convoluted or cavernous abnormal vascular structures may be intercalated between the arterial and venous ends of the malformation. The fast-flow character of AVMs usually becomes evident in childhood or during puberty. Rapid expansion has been reported following pregnancy, trauma, or inadequate surgical intervention. Complications associated with AVMs include cardiac hypertrophy, cardiac failure, and cardiac instability, as well as hemorrhage and stroke.

It is clinically useful to identify three major groups of AVMs, based on structural criteria: truncal, diffuse, and localized. Truncal fistulae arise from major arterial branches and commonly occur in the head and neck; however, trunk and extremity involvement is also seen. Diffuse AVMs are encountered particularly in the limbs and more frequently in lower than in upper limbs. Localized malformations are composed of a mass of abnormal intercalated tissues and can occur in any organ (30,31).

Owing to variations in position, size, length, and number, there is a wide pattern of clinical appearance. Nevertheless, these malformations are recognizable by warmth, a palpable thrill, and an audible bruit. Traditional angiography or MRA to demonstrate their vascular anatomy is essential for confirming the diagnosis and developing a treatment plan (Fig. 104.11).

When a lesion is small and asymptomatic, a period of observation is often the most prudent initial strategy. Unfortunately, however, pain, expansion, ulceration, bleeding, and cardiac decompensation can occur after a quiescent period. If so, more aggressive treatment is indicated. Intraarterial embolization combined with surgical excision currently offers the best chance for cure, but complete excision may be impossible because of location and extent of the malformation. Complex lesions require creative operations tailored to individual pathology and anatomy. When lesions cannot be excised, palliative embolization may be appropriate to control symptoms. Embolization techniques include the use of metal coils, particles, and glue (e.g., *N*-butyl cyanoacrylate). In extremity lesions, amputation may eventually be required. The long-term outcomes of early versus late treatment and the different modalities of treatment are unknown.

HIGHLIGHTS

- All congenital vascular lesions, or more appropriately called vascular anomalies, can be divided into vascular tumors and vascular malformations.
- The most common example of vascular tumors are infantile hemangiomas that present shortly after birth, grow for 6 to 9 months, and then undergo programmed cell death leading to involution.
- Vascular malformations are present at birth and are composed of dysmorphic blood vessels, which grow proportionate with the size of the child and do not involute as the child gets older.
- Kasabach-Merritt phenomenon is associated with kaposiform hemangioendotheliomas and tufted angiomas, and not infantile hemangiomas.
- Most infantile hemangiomas do not require any sort of medical or surgical intervention and require only education of the family and reassurance.
- Infantile hemangiomas that have the potential of causing long-term functional or aesthetic issues should be treated with medicine or surgery.
- Management of vascular malformations is limited mostly to laser, sclerotherapy, or surgical treatment.

Head and Neck Masses in Children

105

Cuneyt M. Alper *Jacob G. Robison*

Primary care physicians commonly encounter children presenting with head and neck masses. Unlike adults in whom a neck mass is considered malignant unless proven otherwise, most pediatric neck masses are benign (1,2). Most generalists are comfortable in treating and following acute inflammatory masses that appear to be benign lymph nodes. However, the vast majority of cases that do not fit this description get referred to a specialist. Although most head and neck masses are benign, they commonly present a diagnostic and therapeutic dilemma to the specialist.

Congenital, developmental, and inflammatory lesions make up most of the masses in the head and neck region. Neoplastic processes comprise 10% to 15% of head and neck masses in children. A retrospective review of 445 children with neck masses revealed that 55% of the masses were congenital, 27% were inflammatory, 5% were noninflammatory benign masses, 3% were benign neoplasms, and 11% were malignancies. In another series of 239 children who underwent cervical lymph node biopsy for nodal enlargement, 49% had idiopathic lymphoid hyperplasia, 37% had infectious lymphoid hyperplasia, and 13% had neoplasms (3). Although malignant neoplasms are not common, cancer ranks second to trauma as a cause of childhood mortality. About 5% to 10% of malignancies originate in, and 25% eventually involve, the head and neck, leading to enhanced concerns of parents and the primary care physicians resulting in early, and sometimes extensive, diagnostic workup and intervention (4). The need for surgical management of the more prevalent congenital masses and benign neoplasms also requires prompt and thorough diagnostic evaluation. Moreover, a number of congenital masses presenting for the first time with an inflammatory exacerbation may enhance the diagnostic and therapeutic challenge.

A practical approach to head and neck masses in children aims to differentiate congenital, inflammatory, and neoplastic etiologies based on location of the mass (Table 105.1). This chapter addresses general approach and differential diagnosis of the head and neck masses in children and covers inflammatory and neoplastic masses. Please refer to Chapter 106 for congenital neck masses and cysts, Chapter 104 for congenital vascular lesions, Chapter 98 for salivary gland disease in children, and Chapter 96 for congenital anomalies of the nose. Coverage of neoplastic pathologies is limited to those that are relatively more prevalent in childhood. Please refer to relevant chapters for the head and neck neoplasms that are rarely seen in the pediatric population.

ASSESSMENT

History and Physical Examination

History

A thorough and systematic history and physical examination are crucial steps for the differential diagnosis. History should focus on age at onset, duration and progression (increasing, decreasing, or stable), constitutional symptoms, and symptoms specific to the mass. More specific symptoms that need to be investigated include skin changes, pain in the region of the nodal swelling, a history of recent upper respiratory tract symptoms, sore throat, otalgia, toothache, insect bites, recent travel, exposure to individuals who are ill, immunization status, and exposure to animals. Answers to these questions will help establish a better differential diagnosis.

Maternal and prenatal history may identify infectious causes of neck masses in neonatal period, such as congenital syphilis or human immunodeficiency virus (HIV). A mass presenting in early infancy may suggest a congenital lesion such as a vascular malformation, branchial cleft cyst, or thyroglossal cyst. Congenital lesions may commonly present later in childhood after becoming infected.

TABLE 105.1 HEAD AND NECK MASSES IN CHILDREN

1) Lateral neck masses
   1 Congenital neck masses (see Chapter 106)
      a) Branchial anomalies
      b) Laryngocele
      c) Thymic cyst
      d) Pseudotumor of infancy
      e) Heterotopic cervical salivary gland tissue
      f) Preauricular pit/sinus/cyst
   2 Inflammatory neck masses
      a) Infectious neck masses
         i) Lymphadenitis
            (a) Acute viral lymphadenitis
            (b) Acute bacterial lymphadenitis
            (c) Mycobacterial lymphadenitis
            (d) Cat-scratch disease
            (e) Fungal, parasitic, and opportunistic infections
         ii) Infectious presentation of congenital mass
         iii) Anatomical site of infection
            (a) Peritonsillar space
            (b) Retropharyngeal space/parapharyngeal space
            (c) Prevertebral space/danger space
            (d) Mandibular space/submandibular sialadenitis
            (e) Masticator space
            (f) Buccal space
            (g) Parotid space/parotitis
      b) Noninfectious inflammatory neck masses
         i) Sarcoidosis
         ii) Kawasaki disease
         iii) Kikuchi-Fujimoto disease
         iv) Rosai-Dorfman disease
         v) Castleman disease
   3 Neoplastic masses
      a) Benign masses
      b) Malignant masses
2) Midline neck masses
   1 Congenital masses (see Chapter 106)
      a) Thyroglossal duct cyst
      b) Dermoid cyst
      c) Plunging ranula
      d) Teratoma of the neck
      e) Thymic cyst or ectopic thymus
      f) Ectopic thyroid
   2 Inflammatory masses
      a) Lymphadenitis
         i) From infections arising from the oral cavity, nasal cavity
      b) Thyroiditis
      c) Infectious presentation of congenital mass
   3 Neoplastic masses
      a) Benign masses
      b) Malignant masses
3) Not site specific
   1 Vascular anomalies (see Chapter 104)
      a) Hemangioma
      b) Lymphatic
      c) Capillary
      d) Venous
      e) Arterial
      f) Mixed

Neck masses in toddlers and later in childhood are most commonly reactive lymphadenopathy. Periodic fever with lymph node enlargement, pharyngitis, and stomatitis should raise the suspicion of Marshall syndrome. Pediatric head and neck masses with a stable duration of months or years are likely congenital lesions or benign inflammatory processes. A history of trauma to the area with or without secondary infection may be found under this sudden presentation. The first presentation of a congenital mass such as lymphatic malformation, thyroglossal cyst, or branchial cleft cyst may also be sudden with rapid enlargement due to infection or hemorrhage.

Temporal presentation of symptoms, as well as anatomical location, is helpful in establishing a differential diagnosis (see Table 105.1). Cervical lymph node enlargement is the most common presentation of a neck mass in children. A thorough history often suggests the probable cause of the cervical lymphadenitis. In general, acute lymphadenitis, which is less than 2 weeks in duration, is due to either a viral or bacterial invasion. A recent viral infection is usually the cause of bilateral or diffuse cervical lymphadenopathy (5). Acute unilateral adenopathy, particularly in infants and young children, may be associated with pyogenic sources such as *Staphylococcus aureus* or group B streptococcal infections. Persistent adenopathy raises more concerns for malignancy but is usually still secondary to an infectious etiology (5). Subacute lymphadenitis, 2 to 6 weeks' duration, has a much broader differential and includes mycobacterial infections, fungal infections, parasitic infections, and many of the noninfectious etiologies as well. However, lymph node enlargement secondary to a variety of viral, bacterial, fungal, or protozoan infections may persist despite appropriate treatment. Enlargement of a salivary gland and pain with eating could suggest ductal obstruction, while more pain with local inflammatory symptoms could suggest sialadenitis with or without ductal obstruction. Rapid growth with fever may suggest acute inflammatory processes such as lymphadenitis, cellulitis, or abscess. Chronic lymphadenopathy, greater than 6 weeks' duration, is more likely to be due to a neoplastic process or invasion by an opportunistic organism (6).

Pediatric head and neck malignancy most commonly present as an asymptomatic neck mass (2). Neck masses that rapidly grow in a month or two should raise the suspicion of malignancy. Enlarging neck masses with systemic signs such as fever, night sweats, and malaise or weight loss suggest a malignant process. Boys have a higher incidence of neck malignancy than girls. Risk factors for malignancy include previous primary cancer, a predisposition to systemic cancer, exposure to carcinogenic drugs, and immunosuppression (7). Previous radiotherapy increases the risk for malignancy, especially thyroid malignancy (8).

Obtaining a family history may provide clues for familial processes such as branchio-oto-renal syndrome or

multiple endocrine neoplasia (MEN) syndromes. While the former often presents with branchial cleft abnormalities in addition to otologic malformations, hearing loss, and renal malformations, the latter may be associated with neuroblastoma or thyroid cancer. A family history for childhood malignancy should alert the clinician for a possible increased risk of malignancy as well.

Physical Examination

Physical examination is important for differential diagnosis. A palpable lymph node in a newborn should be considered abnormal (1). Concern for malignancy should be raised if there is a firm mass in a neonate, skin ulceration, fixation, cranial neuropathies, venous engorgement, a firm mass ≥1 cm in a child under 1 year old, or a firm mass ≥3 cm in a child over 1 year old (3). A neck mass in an infant that cannot be distinguished from sternocleidomastoid muscle with or without head tilt toward and face away from the side of the mass should prompt investigating the fibromatosis colli. Warmth or erythema of the overlying skin suggests infectious process. A draining fistula along the anterior border of sternocleidomastoid muscle suggests a branchial cleft fistula or sinus. Palpation provides information on location and consistency of the mass, whether it is cystic, fluctuant, or solid. A cystic mass in the anterior midline is consistent with a thyroglossal duct cyst; the one at the anterior border of the sternocleidomastoid muscle is likely a branchial cleft cyst. A cystic mass in the posterior triangle is usually a lymphatic malformation. A solid mass in the posterior triangle or supraclavicular region should raise the concern for malignancy. A high proportion of supraclavicular solid masses are due to lymphoma (9). Fixation of the neck mass to the surrounding or deep tissues may be seen with inflammatory or malignant processes (10). Childhood malignant neck masses may be associated with oral or pharyngeal primaries. One in six children with a malignant neck mass has a primary in the oropharyngeal or nasopharyngeal region (11). A thorough examination, including flexible fiberoptic endoscopy, should be performed in order to assess the nasopharynx, oropharynx, hypopharynx, and larynx. For those children that cannot tolerate an adequate outpatient examination, endoscopic examination should be performed under general anesthesia. This thorough exam may be performed concurrent with the neck mass biopsy, if indicated, in order to avoid multiple procedures under general anesthesia.

A number of inflammatory or malignant neck masses may also present with other systemic findings. Horner syndrome should direct attention to the cervical sympathetic chain. Examination of skin may reveal café-au-lait spots consistent with neurofibromatosis or hemangiomas associated with vascular lesions in the neck. Inguinal and axillary lymph nodes and hepatosplenomegaly should be examined. Splenomegaly may be associated with infectious mononucleosis, and a heart murmur with Kawasaki disease.

Laboratory Testing

Assessment of head and neck masses in children may include laboratory evaluation. Laboratory tests are seldom required as part of the workup for acute cervical lymphadenitis. Leukocyte count and markers of inflammation (C-reactive protein and erythrocyte sedimentation rate) are usually abnormal but nonspecific and do not assist in the diagnosis. However, for subacute, chronic, and generalized lymphadenopathy, laboratory evaluation plays a crucial role, and a complete blood count (CBC) with differential should routinely be performed in such conditions. In a more severe acute inflammatory condition such as a neck abscess, a high white blood cell count with higher lymphocytes is expected. Repeated CBC may be utilized to assess the response to the therapy. Atypical lymphocytes should raise the suspicion for infectious mononucleosis, test and heterophile antibody titers (Monospot test) may be used for confirmation.

Serologic tests for *Bartonella henselae*, syphilis, toxoplasmosis, cytomegalovirus (CMV), Epstein-Barr virus (EBV), tularemia, brucellosis, histoplasmosis, and coccidiodomycosis may suggest an infectious agent. Cervical lymphadenitis that is suspicious for either tuberculous or atypical mycobacterial infection should receive a purified protein derivative (PPD) testing. A positive intradermal tuberculin skin test is consistent with an infection due to *Mycobacterium tuberculosis*, but a negative test does not rule it out and will often manifest as a lesser reaction or negative reaction in nontuberculous mycobacterial infections (6). Any material that has been aspirated or collected due to fluctuance should be sent for culture and sensitivity. If history and physical are consistent with possible anaerobic or fungal infections, specific cultures need to be specified.

Neoplastic processes in head and neck may manifest themselves by an abnormal CBC and differential. Blood tests to help identify the cause, or the dissemination, of a malignant process are necessary, such as HIV test, chemistry panel, and a liver panel (4,12). Alkaline phosphatase levels can help determine bone metastasis. Blood urea nitrogen, creatinine, lactate dehydrogenase, and uric acid are adjunct to the workup of lymphomas and other malignancies (13). Cerebrospinal fluid analysis is useful in the workup of central nervous system involvement in malignancies such as lymphoma.

Imaging

Diagnostic radiology is useful for not only narrowing the differential diagnosis of a neck mass but in order to help define the extent of the lesion and assist in preoperative planning. Common modalities include plain radiographs, ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI). Other modalities such as positron emission tomography (PET) and radionuclide scans are also available, but are not widely used, particularly

with regard to inflammatory lesions, and therefore are not be discussed in this chapter.

Plain Radiographs

Radiographic studies are usually not necessary for evaluation of recent onset of masses that appear to be inflammatory. However, persistent or progressively enlarging adenopathy warrants a chest x-ray. A plain chest x-ray may detect pulmonary or mediastinal lesions as a source for cervical or supraclavicular adenopathy (14). Plain radiographs have been supplanted by the use of other more advanced imaging techniques in many situations. Currently, the main use of plain radiographs is for evaluation of the chest for the presence of lymphadenopathy or other pulmonology pathology, as well as soft tissue lateral neck radiographs to assess the airway and prevertebral soft tissue thickening. Initial workup for children with a potential cervical neoplasm should include PA and lateral chest radiograph. This may reveal mediastinal lymph node enlargement as the underlying cause of the airway obstruction or superior vena cava syndrome.

Ultrasound

Ultrasonography has some important advantages for use in the pediatric population; it does not involve ionizing radiation and is readily available (14). Ultrasound is often considered the first-line diagnostic imaging study by many centers (6,15,16). Ultrasound can easily distinguish solid from cystic lesions. Ultrasound is helpful in evaluating the thyroid and parotid lesions and may help diagnosing confusing congenital lesions (14). High-resolution ultrasound is able to assess nodal morphology and internal architecture as well as characterize the echogenic patterns of a mass, classifying them as cystic, solid, or complex in nature. Doppler ultrasound may be used to assess the presence of perfusion and its distribution as well as obtain measures of vascular resistance. Advantages of ultrasound are that it is noninvasive, avoids ionizing radiation, is portable and inexpensive, and can be performed without sedation in most patients. Drawbacks include difficulty to interpret, subject to skill level of operator, may not be able to visualize deeper lesions, and lack of anatomic information for surgical planning (17–19). High-frequency transducers are utilized to evaluate the lymph nodes in the neck as they provide better detail. A normal node as evaluated by ultrasound is a well-defined, elliptical structure with a hypoechoic halo and central sharp linear hyperechoic fatty hilum containing a single vessel (15). Power Doppler imaging of the vascularity of nodes can be useful in differentiating benign from malignant processes. This, however, requires the patient's cooperation, which is sometimes difficult to achieve in young children. Sonographically, neurogenic tumors are elliptical or round hypoechoic solid masses posterior to the carotid sheath vessels in a paraspinal location, with or without intraspinal extension and with or without calcifications (16). Ultrasound does not have a high specificity in distinguishing benign from malignant nodes, and there is significant feature overlap. The features, when combined, that increase the suspicion of malignancy include round shape, absent or eccentric hilum, irregular borders, cystic necrosis, and chaotic capsular blood flow pattern (15). On ultrasound of lymphoma, the enlarged hypoechoic nodes show sharp borders with an absent or eccentric echogenic hilum and a tendency to form masses (20). In Hodgkin lymphoma and non-Hodgkin lymphoma, the affected lymph nodes tend to be round, hypoechoic, and without an echogenic hilum and are likely to demonstrate intranodal reticulation (16). Sonographically, most thyroid cancers are hypoechoic, and the tumor may be irregular and ill defined or smooth and well delineated. A sonolucent rim or halo may completely or partially surround the mass.

Computerized Tomography

Contrast-enhanced CT is the standard of imaging for rapid, accurate diagnosis of an acute deep neck abscesses. In a survey of pediatric otolaryngologist, CT scan was the imaging modality of choice for the evaluation of children with suspected deep neck infections (21). CT is able to differentiate between cellulitis and abscess and is also able to assess the location of the abscess in relation to important anatomical structures, helping to provide a surgical road map (17,22). However, differentiation between phlegmon and abscess is sometimes not easy, and without the addition of intravenous contrast, it is impossible (23). Workup of a neck mass with possible neoplastic characteristics should include CT with contrast of the neck (24). On CT scan, lymph nodes are noted to have homogeneous soft tissue attenuation and present as elongated structures with well-defined, sharp margins with preserved adjacent fat planes and the occasional fatty hilum. However, the internal architecture of nodes is, for the most part, beyond the limits of CT evaluation (15). The CT scan is valuable in differentiating between cystic and solid lesions, establishing the location and exact size of the lesion, identifying other nonpalpable masses, determining the relationship of the mass with the surrounding tissues, assessing bony erosion or remodeling of the bone, and assessing the vascularity within the mass when the study is done with contrast. The high spatial resolution for high-contrast structures makes CT the imaging modality of choice for osseous and fibroosseous lesions in the head and neck (25). On CT, teratomas appear heterogenous, sharply circumscribed, with solid and cystic areas with variable enhancement of the solid component (26). Staging for a number of pediatric malignancies, such as lymphoma, requires CT of the head and neck as well as mediastinum. An abdominal CT scan is used to assess the involvement of the spleen liver and retroperitoneal lymph nodes. On a CT scan, nasopharyngeal carcinoma (NPC) shows a large enhancing mass filling the nasopharyngeal airway (26). CT scan does expose the patient to low doses of radiation, but it is faster than an MRI and, therefore, usually does not require sedation.

Magnetic Resonance Imaging

MRI has the advantage of exquisite sensitivity for soft tissue imaging with excellent anatomic detail. Some studies have shown it to be more successful than CT in distinguishing cellulitis or phlegmon from a true abscess collection; however, CT still remains the standard imaging technique for the evaluation of the acute neck abscess (25,27). Advantages of MRI include the increased sensitivity of soft tissues, ability to provide multiplanar images, and the lack of radiation exposure. Lymph nodes are best seen on fluid-sensitive sequences (T2 or STIR) because they are isointense to muscle on T1 weighting (15). For assessing possible neoplastic masses, MRI provides much greater soft tissue detail and better vascular delineation. Disadvantages of MRI are the need for expensive imaging machinery and obtaining the scan often requires sedation secondary to the longer image capture times necessary. For osseous lesions, MRI can help assess the effect of an osseous lesion on the surrounding structures but should not be seen as a substitute for the CT scan (25). Neurofibromas and schwannomas are heterogenous, isointense to muscle on T1-weighted images, irregularly hyperintense on T1-weighted images, and enhance variably after gadolinium administration. T2-weighted images and fat suppression post–gadolinium-enhanced T1-weighted images are also very helpful (26). MRI has a distinct advantage over CT in evaluating for intracranial extension of tumor. Direct coronal imaging with fat suppression best demonstrates skull base involvement (26). Perfusion MRI is a noninvasive promising method that can be used for differentiation of malignant from benign cervical lymph nodes, and it helps in the characterization of malignant cervical lymphadenopathy (28).

Other

In specific clinical circumstances, radionuclide scans, PET scans, or angiographic scans may be useful. Workup of malignant disease includes searching for distant metastasis. Whole body bone scans are often used in metastatic workup such as for neuroblastoma. If alkaline phosphatase levels are elevated or there is bone pain, bone scans should be done. Gallium scanning is sensitive for identifying the sites of involvement. Recently, fluorodeoxyglucose positron emission tomography has been shown to be superior to the gallium scanning and has become the recommended procedure (29). Bone marrow core biopsies and aspirates are also part of the workup of staging in some malignant tumors such as lymphoma.

Tissue Diagnosis

Fine-Needle Aspiration Biopsy

The use of fine-needle aspiration biopsy (FNAB) in pediatric neck masses is controversial. Percutaneous FNAB is preferred when a preliminary histopathologic diagnosis better guides, modifies, or rules out a definitive surgical procedure, or if the head and neck mass is considered surgically unresectable. The FNAB is not utilized as often as in adults because of limited experience of the cytologist, lack of consensus in diagnostic value for specific malignancies, and concerns with compliance in children when performed without general anesthesia (2,7).

An experienced cytopathologist can differentiate between benign and malignant lesions and may accurately identify the tissue type (30). Similar to adults, anytime there is an indication, and a child can tolerate it, FNAB should be considered (31,32). When the mass is small, deep, or close to vital structures, performing the FNAB under ultrasound or CT guidance may be planned. Often due to noncompliance, a child may need to undergo general anesthesia to obtain the FNAB. If this is the case, the surgeon consults with the pathologist and informs the family that a potentially nondiagnostic FNAB may result that would require a second procedure or that an open incisional or excisional biopsy may need to be performed instead. However, when there is a concern for functional or cosmetic sequelae of an open biopsy, a FNAB may be preferred despite potential inaccuracy or need for a second procedure.

Otolaryngologists facing parents overly concerned with the possibility of malignancy, even when the chance of malignancy is not high, may view FNAB as a compromise between lack of definitive need for open biopsy and chance of eliminating the small risk of malignancy. This may provide comfort to the parents and possibly avoid medicolegal challenges for the delayed diagnosis of a malignancy. Often FNAB can be performed without the need for local or general anesthesia, making it ideal for patients who are unacceptable or poor surgical candidates (30). Occasionally, when there is a chance that multiple lesions may represent different pathologies, or to determine the extent of the disease, FNAB may be performed for the other masses in addition to an open biopsy of the main neck mass. It must be remembered though that FNABs are considered inadequate in establishing the diagnosis of lymphoma (14). In clinical situations when the information obtained from FNAB is not going to affect the decision to remove the neck mass, or change the extent of removal, irrespective of whether it is benign or malignant, there is no need for a FNAB.

Incisional or Excisional Biopsy

An open surgical biopsy may be necessary if there is no diagnosis after a complete evaluation. If the possibility of an inflammatory cause cannot be ruled out, a trial of 2 to 4 weeks of antibiotics is often considered before a biopsy of a neck mass. If the neck mass needs to be removed regardless of the specific pathology, an open surgical excisional biopsy is preferred. When an incisional biopsy is performed, the incision should be planned keeping in mind the need for the further possible exposure during a potential definitive surgical resection.

An open biopsy is indicated when the history, physical examination, and location of a head and neck mass

are suspicious for malignancy. Unusually large masses, those that continue to enlarge after the initial presentation, masses located in the supraclavicular area, or those associated with pain, fever, or weight loss should undergo a thorough workup and open biopsy (10). When there is a high suspicion for malignancy, an open biopsy should be performed, even if there has been a prior negative FNAB. A hematology–oncology consultation may be useful if there is a high suspicion of malignancy.

A frozen section may be planned if the mass is not suitable for total excision due to definite or potential risk for cosmetic or functional sequelae or complication. An intraoperative frozen section is useful to make sure that an adequate representative tissue sample is obtained before terminating the incisional biopsy procedure and the anesthesia. A preoperative consultation with pathology assures readiness for fresh tissue preparations, specific markers, or cell culture. Frozen section is not considered adequate for the diagnosis of lymphoma (14).

A number of pediatric malignancies, including lymphoma, may be associated with lesions in the mediastinum, requiring a focused history and physical examination for the risk of airway compromise during general anesthesia (33). Respiratory collapse under general anesthesia is a complication especially associated with anterior mediastinal masses. Preoperative workup for such risk should include measurement of the tracheal cross-sectional area by CT scans and pulmonary function tests (14). One might consider biopsy under local anesthesia to avoid the risk of airway obstruction with general anesthesia. Alternatively, a rigid bronchoscopy set should be available during induction in such a case to guard against loss of the airway.

INFLAMMATORY MASSES

Inflammatory cervical lymphadenopathy is the most common pediatric neck mass (6). The inflammatory node is usually the result of a recent viral or bacterial infection but may be due to noninfectious etiologies as well. It has been reported that palpable cervical lymphadenopathy occurs with a prevalence of 28% to 55% in otherwise normal infants and children (5). Infectious etiologies for inflammatory head and neck masses in children are listed in Table 105.2.

Infectious Etiologies

Benign cervical lymph node hypertrophy is the most common cause of pediatric neck masses. Clinically palpable cervical lymphadenopathy occurs with a reported prevalence of 28% to 55% in otherwise normal children (5). Children may normally have less than 1-cm palpable lymph nodes. It is not uncommon that children develop idiopathic self-limiting 2- to 3-cm lymph node enlargement. Infectious etiologies are the most common cause of inflammatory cervical lymphadenopathy. Acute bilateral cervical lymphadenopathy is usually caused by viral respiratory tract infections or streptococcal pharyngitis, whereas unilateral cervical lymphadenitis is caused by streptococcal or staphylococcal infection in 40% to 80% of cases (34). Subacute or chronic lymphadenitis may be caused by mycobacterial infections, cat-scratch disease, and fungal,

   - d) *Toxoplasma gondii*
   - e) *Nocardia* sp.

parasitic, or opportunistic infections. Additionally, congenital neck masses may also present with an acute infection of the congenital mass.

Acute Viral Lymphadenitis

Many cases of bilateral cervical adenitis are caused by upper respiratory tract infections of viral etiology, including rhinovirus, parainfluenza virus, respiratory syncytial virus, CMV, EBV, coronavirus, adenovirus, and reovirus. Less common viral agents include mumps, measles, rubella, herpes simplex, human herpes simplex 6 (roseola), and coxsackie viruses (6,35). Involved nodes are usually multiple, relatively small, and without warmth or erythema of the overlying skin. Acute bilateral or diffuse cervical lymphadenopathy is often the result of a recent viral infection and is usually a self-limited process (14). Viral-induced adenopathy rarely suppurates and generally resolves spontaneously over a short period of time (6). Acute viral lymphadenitis is variably associated with fever, conjunctivitis, pharyngitis, and other upper respiratory tract symptoms. Rashes and hepatosplenomegaly may also be present, particularly when CMV is the causative organism. These infections rarely require additional diagnostic testing or specific therapy. Treatment is directed at symptom relief and specific antiviral therapy is seldom indicated except in the rare patient with severe respiratory tract or hepatic involvement, or in the immunocompromised patient (6).

Acute Bacterial Lymphadenitis

Bacterial etiologies of cervical lymphadenopathy tend to be unilateral in nature. While the source of the initial infection may raise the suspicion for specific bacterial organisms, *S. aureus* and group A beta-hemolytic *Streptococcus* (*Streptococcus pyogenes*) are the most frequently isolated bacterial organisms from all cervical sites as a whole (36–39). Bacterial-induced adenopathy tends to produce larger (greater than 2 to 3 cm), solitary, tender, unilateral lymph nodes that rapidly enlarge. Suppurative adenitis indicates an infected lymph node that has undergone liquefaction necrosis. Fluctuance develops in about 25% of patients with acute bacterial adenitis (6,14). Common symptoms include fever, malaise, poor feeding, irritability, and swelling over the infected area with overlying skin erythema.

Over the past 10 to 15 years, there has been a sharp increase in the number of methicillin-resistant *Staphylococcus aureus* (MRSA) cases that have been reported. Reports from different hospitals/geographical areas indicate a 6% to 65% (22,39–43) increase in incidence with time, and reports of resistance to other antibiotics have varied. With this trend noted, selection of an appropriate antibiotic for treatment needs to address the local incidence and antibiotic susceptibility of the common offending organisms. Usually antibiotics that are beta-lactamase stable or those that inhibit beta-lactamase are most desirable. The combination ampicillin–sulbactam has been used with good success in multiple studies and has activity against gram-positive, gram-negative, and anaerobic bacteria (44–46). When the patient has improved sufficiently to change from intravenous to oral therapy, the oral form of ampicillin–sulbactam, the prodrug sultamicillin, as well as amoxicillin–clavulanate are appropriate agents. Other good choices include cefuroxime axetil, cefprozil, and clindamycin. If there is suspicion for MRSA, recent studies have shown the majority of the community-acquired MRSA is still sensitive to clindamycin and Bactrim (22,43).

Anaerobic bacteria may be found in older children with dental caries or periodontal disease. The most commonly isolated anaerobic bacteria are *Bacteroides* sp., *Peptococcus* sp., *Peptostreptococcus* sp., *Propionibacterium acnes, Fusobacterium nucleatum, Eikenella corrodens*, and *Prevotella* sp. (6,47). Other more rare bacterial isolates include gram-negative bacilli such as *Francisella tularensis, Pasteurella multocida, Yersinia pestis, Haemophilus influenzae, Klebsiella* sp., *Serratia marcescens*, and *Moraxella catarrhalis* (6,36,39). Treatment of these bacteria is dependent on their individual susceptibility to antibiotics, though clindamycin usually has good coverage against the anaerobic bacteria, but poor coverage against gram-negative organisms. Ampicillin–sulbactam, or its oral form sultamicillin, is another good choice for these organisms with its broad range of coverage that includes anaerobic and gram-negative bacteria (45,46).

Mycobacterial Lymphadenitis

Chronic cervical lymphadenitis may be caused by *M. tuberculosis* or by nontuberculous strains of mycobacteria (*M. avium–intracellulare, M. scrofulaceum, M. kansasii, M. fortuitum*, and *M. hemophilum*). In the United States, 70% to 95% of cases of mycobacterial lymphadenitis are due to nontuberculous strains (6). Characteristic presentation includes rapid onset of nodal enlargement followed by a gradual increase in nodal size over 2 to 3 weeks. Constitutional signs are unusual, but a characteristic change of the overlying skin to a pink to lilac-red hue is common. Approximately 50% will develop fluctuance and spontaneous drainage occurs in about 10% (6). The definitive treatment for nontuberculous strains is surgical excision (6,48), but there is increasing evidence that macrolide antibiotics may be beneficial (49). With *M. tuberculosis*, multiagent antituberculous antibiotic therapy for 12 to 18 months is standard treatment.

Cat-Scratch Disease

Cat-scratch disease is a lymphocutaneous syndrome characterized by regional lymphadenitis associated with a characteristic skin lesion at the site of inoculation. It is caused by inoculation of the bacteria *B. henselae* through broken skin or mucous membranes. The most common sites of lymphadenopathy are the axilla (52%) and the neck (28%) (6). Clinically, patients typically present with a single large (greater than 4 cm) tender node with suppuration in 30% to 50% of cases (50). Constitutional symptoms are usually mild and include low-grade fever, body aches, malaise,

or anorexia. Standard for diagnosis is serologic testing for antibodies to *Bartonella*. In the immunocompetent patient, cat-scratch disease is usually self-limited with spontaneous resolution after 1 to 3 months. However, a study has shown azithromycin to be associated with more rapid resolution of nodal enlargement (51,52).

Fungal, Parasitic, and Opportunistic Infections

The soil saprophytes *Histoplasma capsulatum, Blastomyces dermatitidis*, and *Coccidioides immitis* are endemic to certain geographic regions of the United States and can cause fungal infections in humans. Most patients will have pulmonary infections with secondary cervical lymphadenopathy. Diagnosis is through serologic or skin testing. Most infections do not require treatment and resolve spontaneously. Patients with severe respiratory or systemic symptoms may require prolonged courses of antifungal therapy (6,14).

Infection with the intracellular protozoan *Toxoplasma gondii* can present with cervical, suboccipital, supraclavicular, axillary, or inguinal adenopathy. Involved nodes may be tender but do not suppurate. Diagnosis is by culture or serologic testing. Most patients do not require antimicrobial therapy, but if symptoms are severe or persist, treatment is with a combination of pyrimethamine, sulfadiazine, and leucovorin for at least 4 to 6 weeks (6).

Infections caused by *Nocardia* sp. are infrequent and usually present as lung disease in immunocompromised hosts. Infection usually occurs through inhalation or direct skin inoculation. Diagnosis is through culture of the skin pustules or involved nodes. Sulfonamides are the treatment of choice (6).

Infected Congenital Masses

Congenital masses also may become acutely infected. Infected congenital masses should be included in the differential diagnosis, particularly in the absence of a dental or pharyngotonsillar cause, or in recurrent neck infections (53). Thyroglossal duct cysts, the most common congenital neck anomaly, will become infected 40% to 60% of the time (54). It has also been reported that any unilocular, nontranslucent cystic swelling in relation to the deep anterior portion of the sternocleidomastoid muscle is very suggestive of an infected brachial cyst (53). A history of recurrent neck infections with multiple incision and drainage procedures may represent a congenital sinus tract that has never been completely excised. Diagnosis usually is made by utilization of CT scans (17,53). The use of a barium swallow for diagnosis of a pharyngeal fistula/sinus tract also has been reported (55). Treatment consists of IV antibiotics and surgical excision of the congenital lesion. Some controversy exists with regard to timing of surgical treatment. Some authors promote treatment with antibiotics for at least 6 weeks for resolution of the infection/inflammation prior to surgical excision (56), and others advocate for immediate surgical excision with concomitant treatment with antibiotics (53).

Characterization of Infection By Anatomical Location

The location of the enlarged lymph node(s) is a good indication of the likely site of entry of the offending organism. Involvement of superficial nodes usually indicates an epithelial surface (i.e., buccal mucosa, skin, scalp, etc.) as the site of entry, whereas deep nodal enlargement results from an infectious process arising from more central structures such as the posterior pharynx or middle ear (6). Each of the following anatomical subsites has specific sites of origination of infection as well as common presenting signs and symptoms.

Peritonsillar

The peritonsillar space lies between the capsule of the palatine tonsil and the pharyngeal muscles. It is the most common site of head and neck space infections (36). Peritonsillar infections originate from the oropharynx and may spread by direct communication to the lateral pharyngeal space. Clinical findings usually include pain, fever, dysphagia, trismus, and cervical adenopathy. Physical examination shows swelling of the tissues lateral and superior to the tonsil with subsequent medial and anterior displacement of the tonsil and medial displacement of the uvula. Medical treatment includes antibiotics with some evidence that steroids help with subjective symptoms (57). Differentiating between peritonsillar cellulitis versus abscess may not be straightforward. Otolaryngologists rarely order a CT scan for this condition. However, if performed, rim enhancement at the wall of hypodense center would indicate an abscess. When there is no imaging available, clinical judgment should suspect an abscess with the severity of inferomedial displacement of the tonsils, with an obvious bulge at the superolateral aspect of the tonsil, and most importantly with the presence of significant trismus. Surgical treatment options include incision and drainage, needle aspiration, and immediate tonsillectomy (quinsy tonsillectomy). All three options have been shown to be efficacious and safe, but definitive proof of superiority for any one of them has not been established, and each continues to play an important role in managing these abscesses (57–60).

Retropharyngeal/Parapharyngeal Space

The retropharyngeal space lies posterior to the buccopharyngeal (visceral) fascia covering the pharynx and anterior to the alar fascia. The buccopharyngeal fascia is adherent to the alar fascia in the midline so infections are usually unilateral in nature. The lymph nodes in this area receive drainage from the nose, paranasal sinuses, pharynx, and eustachian tube. The parapharyngeal space is bounded by layers of deep cervical fascia. The space resembles an inverted pyramid with the base at the skull base and the apex at the level of the hyoid bone. Anterior and posterior compartments are separated by the tensor veli palatini

tendon and fascia. Parapharyngeal space contains many important neurovascular structures, including cranial nerve V3, internal maxillary artery, deep lobe of the parotid gland, great vessels, cervical sympathetic chain, and cranial nerves IX to XII. Due to the close proximity of the parapharyngeal and retropharyngeal spaces, with frequent extension of infection from one space to another, these spaces will be considered together.

Clinical presentation of an inflammatory process in these spaces usually includes irritability, fever, dysphagia, muffled speech or cry, noisy breathing, torticollis, and stiff neck. Stridor and drooling may develop later if left untreated. Physical exam findings include unilateral posterior pharyngeal swelling for retropharyngeal abscesses; however, significant swelling of the contralateral side of the pharynx can give the impression of symmetric swelling. A CT scan for assessment of extent of disease is usually necessary and is helpful in presurgical planning (61). Surgical approaches include both transoral and lateral external routes for incision and drainage, with transoral approaches more commonly employed (58,61,62). Recent advances in antimicrobials have led to multiple studies advocating for initial medical management with intravenous antibiotics, reserving surgical intervention for those patients who fail medical treatment (60,61,63–65).

Prevertebral Space/Danger Space

Prevertebral space is located between the prevertebral layer of the deep cervical fascia and the alar layers of the deep cervical fascia. There is some controversy as to whether or not there is a space between the vertebral bodies and the prevertebral fascia and whether there are two distinct spaces separated by the prevertebral layer of the prevertebral fascia. Here, space between the vertebra and the alar fascia is discussed as a common space named as prevertebral space. Prevertebral space extends from the cranial base to the level of the diaphragm, which facilitates the spread of neck infection into the mediastinum making it the "danger space." Infection may spread to this space from the vertebral bodies. Clinically, these infections are seen as a bulging mass in the midline of the pharynx with extension to both sides of the pharynx due to the absence of a midline raphe (different from the retropharyngeal space). Surgical approaches are through open external approaches in order to help prevent a persistent draining fistula into the pharynx, better access to the frequent lateral extension of the infection/abscess, and the possible need to debride osteomyelitic lesions of the vertebral column (66). If the infection arises from a tuberculous infection of the vertebral bodies, prolonged antimicrobial therapy also may be needed (67,68).

Mandibular Space

The mandibular space is formed by splitting of the two leaflets of the superficial layer of the deep cervical fascia. These leaflets attach to the inferior border of the mandible on its lateral surface and the medial surface of the mandible at the level of the mylohyoid muscle. The space is limited anteriorly by the attachment of the anterior belly of the digastric muscle and posteriorly by the attachment of the medial pterygoid muscle to the mandible. Infections in this area usually follow dental infection, trauma, or surgery. Pain and intraoral swelling are present but no external facial swelling is noted unless the infection involves the dependent lymphatics in the submandibular space. Drainage of the abscess may be done via an intraoral incision along the medial surface of the body of the mandible (68).

Submandibular Space/Submandibular Sialadenitis

The submandibular space is a continuation of the lateral pharyngeal space at its most anterior extent. The limits of the space are the mucosa of the floor of the mouth and the tongue superiorly and the superficial layer of the deep cervical fascia inferiorly. This space is sometimes subdivided into submaxillary space and the sublingual space by location superior (sublingual) or inferior (submaxillary) to the level of the mylohyoid muscle. The submaxillary space may be further subdivided into the submental space and the subsidiary submaxillary space by the anterior bellies of the digastric muscles. Infections in this space arise primarily from mandibular dental disease but may also result from sialoadenitis, suppurative adenitis, or tonsillar disease. Infections in these spaces may progress to abscess formation or persist as cellulitis. Bilateral involvement of the submandibular spaces can lead to massive edema of the tongue and floor of the mouth with posterior displacement of the tongue. This may lead to respiratory compromise. Patients frequently have halitosis and difficulty handling their secretions. This constellation of signs and symptoms is called Ludwig angina. Surgical treatment is based on the principle of releasing tension. It is important to perform adequate exploration for abscesses and to drain them, since they may be loculated. Even if imaging studies do not show an abscess, open surgical intervention is recommended in all but an exceptionally mild, early case. Surgical control of the airway via tracheotomy is considered strongly in all but exceptional mild cases as well. The surgical approach includes a generous horizontal incision approximately 1 cm above the hyoid bone (68).

Masticator Space

The masticator space is created by the splitting of the superficial layer of the deep cervical fascia around the masseter and internal pterygoid muscles. The space ends posteriorly at the posterior border of the mandible, superiorly at the origin of the temporalis muscle, laterally at the temporalis fascia, and medially it extends into the pterygopalatine fossa. Infections most commonly arise from the mandibular teeth and usually are related to dental infection, trauma, or surgery. Symptoms include deep pain along the ascending ramus of the mandible, trismus, sore throat, dysphagia, and pain with tongue movement. Swelling may

be present either in the area of the retromolar trigone or, externally, overlying the masseter muscle and mandible. If medial swelling/infection is present, an intraoral incision medial to the ascending ramus of the mandible is used to drain the abscess. If lateral/external swelling is present, an open approach with an incision just below the mandible is often utilized (68).

Buccal Space

The buccal space is lateral to the buccopharyngeal fascia and medial to the skin of the cheek. The inferior limit is the lower border of the mandible, and the posterior limit is the pterygomandibular raphe. Infections here arise from dental infections of both the maxillary and mandibular teeth. Clinically, infections are characterized by marked swelling of the cheek, which is typically warm, tender, and red. Trismus may be present if the inflammation extends to the masseter muscle. Usually abscesses occur subcutaneously. These are treated with surgical incision and drainage through an external approach and appropriate antimicrobials (68).

Parotid Space/Parotitis

The parotid space is formed by splitting of the superficial layer of the deep cervical fascia to cover the medial and lateral surfaces of the parotid gland. The medial fascia is thin and allows parotid space infections to extend into the adjacent lateral pharyngeal space. The lateral fascia is much thicker and tougher and usually prevents the palpation of fluctuation in the parotid space. Infections in this space arise from dental infection of the mandibular teeth, parotid gland infections, or suppurative adenitis of lymph nodes contained within the space (68). Infections that arise from within the parotid gland (parotitis) are usually due to blockage/obstruction of salivary outflow by thick secretions, sialoliths, or compression of the duct by external mechanisms. Inflammation of the gland from other etiologies such as viral infection (measles, mumps), Sjögren syndrome, or sarcoidosis also may lead to blockage of salivary flow (69,70). Treatment of early parotitis with warm compresses, hydration, massage, antibiotics, and release of the salivary obstruction (also includes treatment of intraparotid inflammation from viral infection or other inflammatory disorders) is necessary to prevent progression to abscess formation (71,72). Once an abscess is formed, the surgical approach for drainage is through a standard parotidectomy-type incision (71). If extension into the parapharyngeal space is present, this same approach may be utilized (68).

Noninfectious Etiologies

Cervical lymph node involvement may be a manifestation of a systemic disease with an inflammatory component. Most of these diseases are very rare but a brief description of several of the more common diseases follows. This list is not meant to be all-inclusive.

Sarcoidosis

Sarcoidosis is a chronic noncaseating granulomatous disease of unknown etiology. The lung is the most common organ involved but any organ can become involved. The most common finding on physical exam is peripheral lymphadenopathy. Cervical nodes tend to be bilateral, discrete, firm, and rubbery. Supraclavicular nodes are involved in more than 80% of patients (6). Diagnosis is via biopsy with histologic examination. Treatment is usually supportive in nature but corticosteroids may suppress acute manifestations (6,73).

Kawasaki Disease

Kawasaki disease is an acute febrile vasculitis of childhood of unknown etiology. One of the earliest manifestations is lymphadenitis. Involved nodes are usually unilateral, confined to the anterior triangle, and only moderately tender and are nonfluctuant (6). Diagnosis is made clinically based on the presence of a fever for at least 5 days in the presence of several other characteristic clinical features (polymorphous rash, conjunctival injection, red lips, red tongue, oropharyngeal erythema, erythema or cracking of the lips, indurative edema of the hands and feet, and diffuse erythema of the palms and soles (74)). Twenty-five percent of patients will present with cervical lymphadenopathy (75). Treatment is with salicylates and intravenous immunoglobulin (74), but infectious diseases and cardiology consults are also necessary since this is a clinical diagnosis with significant morbidity if not diagnosed and treated accordingly. One of the more devastating effects of this disease is coronary artery lesions. Kawasaki disease has now become the most common cause of acquired heart disease in children in the United States (74). However, there does not appear to be any association between cervical lymphadenopathy presence/severity and risk for development of coronary lesions (76). Resolution of the cervical lymphadenopathy usually occurs early in the course of the disease.

Kikuchi-Fujimoto Disease

Kikuchi-Fujimoto disease is a necrotizing lymphadenitis of unknown etiology. It usually presents with bilateral, enlarged, firm, painful lymph nodes in the posterior cervical triangle (77,78). Associated findings include skin lesions, fever, nausea, weight loss, night sweats, and splenomegaly. Diagnosis is made by biopsy with histologic examination. Treatment is symptomatic in nature with corticosteroids reserved for more severe cases. Most cases will resolve spontaneously in 1 to 4 months (6,78).

Rosai-Dorfman Disease

Rosai-Dorfman disease is also known as sinus histiocytosis with massive lymphadenopathy. It is a rare disorder of unknown etiology, which usually presents with mobile, discrete nontender nodes, which then progress to massive bilateral cervical nodal enlargement. Ninety-seven percent of patients have cervical lymphadenopathy and 30% will

have lymphadenopathy elsewhere. Thirty to forty percent will have extranodal manifestations, with 75% of those occurring in the head and neck regions. Extranodal manifestations include involvement of the skin, orbits, eyelids, salivary glands, upper respiratory tract, thyroid, peritoneum, bone, kidney, testes, and the central nervous system (79,80). Laboratory evaluation will show hypergammaglobulinemia. Diagnosis is based on biopsy or fine-needle aspiration (81), with histologic evaluation demonstrating florid hyperplasia, marked histiocytosis, plasmacytosis, and phagocytosed lymphocytes (emperipolesis) (79). Resolution usually occurs after 6 to 9 months but an indolent course with periodic remissions and exacerbations is also possible (80). However, extensive or progressive disease may require treatment with combination chemotherapy or corticosteroids. Surgery is reserved for diagnostic biopsy or relief of obstructive symptoms (79,80).

Castleman Disease

Castleman disease is a rare lymphoproliferative disorder of unknown etiology. There are two distinct histologic types, hyaline–vascular and plasma–cell (82). The disease may present as either localized or multicentric. The chest is the most common location affected with the neck as the second most common site (82,83). The localized form is 90% hyaline–vascular type and usually has a solitary mass that follows a benign course (83). The multicentric form usually is the plasma–cell type and is accompanied by systemic illness, disseminated lymph nodes, constitutional symptoms, autoimmune abnormalities, recurrent infections, and laboratory abnormalities (83,84). The multicentric form is aggressive and often culminates in death secondary to infectious complications or malignancy (33% of Castleman disease patients will develop malignancies (84)). Diagnosis is made through surgical biopsy with histologic examination. Of note, fine-needle aspiration usually leads to misdiagnosis, frequently being confused with lymphoma (82). Treatment is dependent on the extent of disease. For localized disease, complete surgical resection is the treatment of choice, with radiotherapy as an alternative (85). Incomplete resection can lead to recurrence (83). For multicentric disease, combination chemotherapy, with or without steroids, is the best option for treatment. Treatment with monoclonal antibodies against IL-6 has been shown to alleviate symptoms, but symptoms return upon stopping the therapy (86).

NEOPLASTIC MASSES

Evaluation of neoplastic pediatric head and neck masses requires broad knowledge of head and neck embryology and anatomy, a clear understanding of the varied differential diagnosis of these lesions, and an orderly and thorough history and physical examination to help direct evaluation and management. Neoplastic head and neck masses in children are listed in Table 105.3. Although masses of this

region are common, very few are malignant. Appropriate radiographic and laboratory evaluation for suspected or diagnosed malignancies are essential. When malignancy is confirmed, a multidisciplinary team including the surgeon, pediatric medical oncologist, radiologist, and pathologist should be assembled to facilitate staging and an appropriate treatment strategy (13).

Benign Head and Neck Neoplasms

Teratomas

Teratomas are the most common congenital tumors with elements derived from all three germ cell lineages in various degrees of differentiation. Teratomas arise in a variety of locations throughout the body. Most are sacrococcygeal, with cervical teratomas representing less than 10% (87). Most teratomas are benign. The head and neck region is the second most common site for teratomas in infants, usually presenting at birth or even prenatally. Teratomas of the head and neck occur in the nasopharynx, oral cavity, orbit, neck, and thyroid (88). The unusual size of teratomas, along with their intracranial location during intrauterine development provides a combination that often is not compatible with life (89). After birth, teratomas may present as large neck masses that cause airway obstruction. Imaging studies demonstrate a large, heterogenous mass that has both cystic and solid components (26). The diagnosis is usually obvious at birth, but due to the widespread use of prenatal ultrasound, there has been an increase in the diagnosis of fetal neck masses, particularly airway-threatening lesions. Prenatal diagnosis may be made with ultrasound or MRI. With the prenatal diagnosis of a large mass that is expected to cause life-threatening airway obstruction, an *ex utero* intrapartum therapy procedure is planned in order to secure the airway via a C-section during ongoing placental perfusion (14,90).

Neural Tumors

Neurofibromas and schwannomas are benign tumors of the peripheral nervous system. Neurofibromas may originate from any of the cranial, peripheral, or autonomic nerves. They may present as solitary masses; however, they more commonly present as multiple masses associated with a systemic genetic condition such as neurofibromatosis type I (NF-1, von Recklinghausen disease), neurofibromatosis type II, or other less common forms. Nearly all children with head and neck neurofibromas are diagnosed with NF-1 (26). Neurofibromatosis type I (85% of the NF patients) has an incidence of 1:4,000 live births and has autosomal dominant inheritance with variable penetrance. About 50% of cases are new mutations (91). Approximately 33% of the NF-1 patients have otolaryngologic manifestations, including neck masses that impinge upon the airway. Superficial neurofibromas may present as nodular or pedunculated lesions, while plexiform neurofibromas occur deep in the neck, sometimes expanding toward the oropharynx or hypopharynx. Plexiform neurofibromas traditionally have posed a surgical challenge in pediatric patients. Expert preoperative planning, advanced surgical techniques, and vigilant postoperative care result in minimal morbidity and resolution of tumor symptomatology (92). Neurofibromatosis type II occurs at a frequency of 1 in 50,000 live births, usually presenting as bilateral tumors of the eighth cranial nerve.

Schwannomas originate from the peripheral nerve sheath. They usually present as solitary encapsulated masses. Approximately 40% to 50% of all schwannomas manifest in the head and neck, with the lateral neck being the most prevalent site (93). Although benign, these lesions can cause secondary symptoms relevant to the location of the lesion, including nasal obstruction, dysphagia, and hoarseness (94). In the lateral neck, the vagus nerve and cervical sympathetic chain are the most commonly affected nerves. Treatment is complete surgical excision with preservation of the underlying nerve if possible. Treatment of schwannomas by enucleation may be the most reliable function-sparing technique of these slowly growing benign neoplasms (95).

Lipomas

Lipomas present as a slowly enlarging, relatively soft, asymptomatic, subcutaneous mass in the cervical region. Rarely, a deeply located lipoma may compress the aerodigestive tract. Treatment is complete surgical excision.

Pilomatrixoma

Pilomatrixomas are firm, nontender, intradermal, or subcutaneous masses. Also known as a calcifying epithelioma of Malherbe, histopathologically they are hamartomas of hair follicle origin. High-density calcium deposition, or calcification, is responsible for the firmness of the masses. About 60% of pilomatrixomas occur in the head and neck region and 40% occur in children under 10 years of age (96). They are considered benign masses without malignant potential. Surgical excision is diagnostic and curative. However, pilomatrixomas are variable in size and location, occasionally making surgical excision cosmetically challenging.

Fibromatosis Colli

Fibromatosis colli or congenital muscular torticollis presents in the neonatal period with a firm mass within the sternocleidomastoid muscle. Affected babies aged 2 to 4 weeks present with a unilateral, often rock-hard, anterior neck mass, which is right sided in 75% of cases (16). Often it is noticed several weeks after birth with turning of the infant's face in the opposite direction and tilting of the head toward the mass. Birth trauma such as breech delivery or use of forceps may have taken place although it can be seen in births with atraumatic vaginal delivery or C-section (97). Hemorrhage within the muscle followed by fibrosis is thought to be responsible for the shortening

of the sternocleidomastoid muscle and the resulting torticollis. Ultrasound or CT scan is usually necessary to rule out malignancy or a congenital lesion and confirm the diagnosis. Rarely, if imaging is not typical or diagnostic, a FNAB may be necessary. The mass usually resolves within 4 to 8 months (16). When torticollis is present, physical therapy is recommended. About 10% to 20% of children may progress to persistent muscular torticollis with risk of craniofacial deformity (98). If fibromatosis colli persists beyond 12 months of age despite adequate physical therapy, or there are early signs of developing craniofacial asymmetry, surgical intervention with release of the muscle is indicated (99).

Malignant Head and Neck Masses

By far, the most common head and neck malignancy in children is lymphoma. Rhabdomyosarcoma (RMS), neuroblastoma, and teratoma account for the majority of the other malignant pediatric neck lesions (14).

Lymphoma

Over half of pediatric neck malignancies are lymphomas (3,9). Lymphomas represent 13% of newly diagnosed childhood cancers (12,100). Lymphomas account for only 3% of the cancers in children younger than age 5 years and 24% of the cancers in children 15 to 19 years of age. It is unlikely that lymphoma will occur before 3 years of age. Lymphoma manifests itself in two distinct histopathologic and clinical types, Hodgkin disease and non-Hodgkin lymphoma.

Hodgkin disease is a malignancy of the lymphoreticular system, commonly presenting in the cervical region in adolescents and young adults with less than 10% occurring in children younger than 15 years old. Boys are affected twice as frequently as girls. More than 80% of the patients present with asymptomatic, firm, rubbery cervical lymphadenopathy, especially in the supraclavicular fossa. Involvement of mediastinal lymph nodes is common and may be noted by symptoms associated with compression of the airway or superior vena cava. Hodgkin disease may be associated with nonspecific symptoms such as fever, night sweats, weight loss, weakness, anorexia, and pruritus. The Ann Arbor staging classification system is utilized to determine the stage of disease and the treatment protocol (see Chapter 128). Immunohistochemical techniques performed on biopsy samples are capable of distinguishing lymphoid from epithelial, mesenchymal, or neural proliferations (101). After diagnosis, treatment, including chemotherapy, radiotherapy, or both, generally achieves over 90% initial complete remission. Long-term outcome is dependent on the stage of the disease at the time of diagnosis (102).

Non-Hodgkin lymphoma is a primary lymphoreticular system neoplasm consisting of a heterogeneous group of solid tumors presenting primarily in the pediatric population between 2 and 12 years old. Non-Hodgkin lymphomas comprise about 60% of the newly diagnosed lymphomas (12). Parents with congenital or acquired immunodeficiency and EBV are associated with non-Hodgkin lymphoma (12). Unlike Hodgkin disease, non-Hodgkin lymphoma often presents with advanced disease already involving multiple systemic sites including the head and neck region (12). In general, the majority of patients present with painless lymphadenopathy. However, in children, the usual presentation is rapidly growing extranodal disease that involves the head, neck, and mediastinum. Lymphoid tissue of Waldeyer ring commonly is involved (103). The early detection of non-Hodgkin lymphoma may be difficult due to prevalent symmetric or asymmetric enlargement of the tonsils and adenoids in otherwise healthy patients. Although nonspecific, attention to the associated symptoms is essential to avoid delay in diagnosis. Respiratory distress or superior vena cava syndrome requires prompt evaluation. Dissemination is hematogenous and nearly two-thirds of children have locally advanced or metastatic disease at the time of diagnosis (12). Systemic symptoms of malaise, weight loss, and fever are associated with more advanced disease. Central nervous system spread manifests itself with cranial nerve palsies, mental status changes, and pleocytosis. Pancytopenia is associated with bone marrow involvement and greater than 25% of the bone marrow replacement is associated with leukemic transformation (12). Incisional or excisional biopsy for special staining leads to classification of the non-Hodgkin lymphoma into B-cell, T-cell, and histiocytic categories and into further subtypes based on morphologic appearance and the degree lymphocytic transformation (see Chapter 128). The resulting classification and grading system helps predict the response to therapy and the outcome. Histologic type, leukemic transformation, hematogenous dissemination, and central nervous system involvement all indicate poor prognosis. Since systemic dissemination results in frequent advanced stage at presentation, systemic chemotherapy is the primary treatment modality in children. Multidrug chemotherapeutic protocols have resulted in improved survival rates (12). Surgery is reserved for patients with aerodigestive compromise that may benefit from debulking. The prognosis is excellent for children with limited disease regardless of subtype. Despite significant improvements in outcome of advanced stage non-Hodgkin lymphoma, nearly 30% of patients relapse or never achieve a first remission, which is indicative of a poor prognosis. Patients that have a second remission are considered candidates for bone marrow transplantation (12).

Posttransplant Lymphoproliferative Disease

Diffuse enlargement of lymphoid tissues or, less commonly, a solid tumor may be seen in immunosuppressed pediatric transplant patients (104). While this may be indistinguishable from normal adenotonsillar hypertrophy, it

may also present with tan-brown adenotonsillar discoloration (105). Significant adenotonsillar hypertrophy or paratracheal compression may lead to airway compromise. Treatment consists of reducing immunosuppressive therapy and usually results in disease resolution.

Rhabdomyosarcoma

The most common pediatric soft tissue malignancy of the head and neck is RMS, accounting for 50% to 70% of all childhood sarcomas (106,107). Seventy percent of those children have disease before the age of 12, and 50% are younger than 5 years of age (108). The disease has a peak presentation at 2 to 5 years and again at 15 to 19 years with a slight male predominance (26). RMS manifests itself in the head and neck in 35% to 40% of the cases, including the orbit, nasopharynx, middle-ear, mastoid, and sinonasal cavities (4). Presenting symptoms include nasal airway obstruction, bloody rhinorrhea, otorrhea, and proptosis. Delay in diagnosis is not unusual due to the varied sites and nonspecific symptoms. Direct intracranial extension or lymphatic and hematogenous metastasis may be present. Metastasis from nonorbital RMS to cervical lymph nodes is seen in 8% of children and distant metastasis is seen in 13% (109).

The diagnosis of RMS generally requires either a core needle biopsy or open biopsy to obtain adequate tissue for pathologic and molecular analysis (13). The clinical staging system is based on the extent of the disease and whether excision of the local or regional disease is performed (110). Surgical excision is recommended for localized disease as it improves survival and, if complete, avoids the need for radiotherapy, which is associated with a high risk of morbidity in children (such as facial growth retardation and second neoplasm). In large or extensive RMSs of the head and neck in which the morbidity of surgical resection is excessive or complete resection is unobtainable (e.g., nasopharynx, paranasal sinuses, and temporal bone), or both, treatment with combination chemotherapy and radiotherapy is indicated (111). Multimodal therapy including surgery and radiotherapy is used to control the local and regional disease while chemotherapy is used to control the distant metastases. Surgical resection is performed if this does not lead to major functional compromise. For orbital or other nonresectable RMS, biopsy is the only indicated surgery. If there are no neck metastases, the patient is followed after receiving chemotherapy. If there are enlarged lymph nodes, a neck dissection is indicated, and if the nodes are positive, additional radiotherapy is performed. The main prognostic factor is presence or absence of metastatic disease (110). RMSs may directly erode through bone or extend through skull base foramina via perineural spread to develop epidural masses and, sometimes, meningeal involvement (26).

Those individuals without metastatic disease may have greater than 90% survival rates. Patients with locally invasive, unresectable, but nonmetastatic, disease also can expect a 60% to 70% long-term survival rate. The survival rates for advanced disease also have improved in the recent years (112). More than 80% of patients with RMS of the head and neck are cured of their disease using surgery and vincristine, dactinomycin, and, in some cases, cyclophosphamide with or without radiotherapy. Early, limited exposure to cyclophosphamide might reduce recurrence in low-risk embryonal patients, and that reduced dosage might achieve comparable results with improved toxicity profiles (113). Orbital location of disease has the best prognosis and parameningeal disease has the worst (26). Multimodality therapy for head and neck RMS can result in dentofacial abnormalities that affect the patient's quality of life (114).

Other Soft Tissue Sarcomas

Sarcomas other than RMS are rare in childhood. Sarcomas account for less than 1% of all malignancies in the United States with only 5% to 15% of these sarcomas occurring in the head and neck region. However, about one in three pediatric sarcomas will occur in the head and neck region. Occasionally, these tumors are associated with genetic syndromes or previous radiation exposures, but more commonly, no clear etiology exists (115). Pathologic classification is critical to the ultimate treatment and prognosis of sarcoma of the head and neck. Osteosarcoma, rhabdomyosarcoma, malignant fibrous histiocytoma, and angiosarcoma are the most common types of sarcoma to occur in the head and neck region; however, up to 20% of head and neck sarcomas will remain unclassified. Other sarcomas are also tumors of mesenchymal cell origin, including leiomyosarcoma (smooth muscle), liposarcoma (fat), and fibrosarcoma (connective tissue). Diagnostic approaches to non-RMS soft tissue sarcomas are essentially the same as for RMS. Because of their extreme rarity, there is no meaningful staging system to guide therapy

Neuroblastoma

Neuroblastoma is the second most common solid tumor of childhood. Neuroblastoma accounts for the most common neck malignancy under 6 years of age (107). Neuroblastoma commonly presents as a solitary painless mass or lymphadenopathy (116). Cervical neuroblastoma may occur as a primary tumor but is more commonly a site of metastatic disease from an abdominal or thoracic primary tumor (14). Pain from bone metastases, Horner syndrome, or proptosis also may be present. Prognosis is related to age at presentation, stage, and lymph node metastasis. Treatment is based on the degree of regional extension and systemic dissemination and includes surgical excision, with or without chemotherapy and radiotherapy. In cases with delayed diagnosis and advanced disease, nonsurgical options with or without autologous bone marrow transplant are also considered. Localized lesions or low-stage disease has an excellent prognosis with complete surgical resection. Radiation therapy or chemotherapy, or both, and secondary surgeries are strategies to eradicate residual disease. Primary cervical neuroblastoma

has a favorable outcome (13,14). Children younger than 1 year of age and older children with localized disease have an excellent prognosis (117).

Thyroid Malignancies

Thyroid malignancies used to account for 50% of the pediatric neck malignancies (107). However, with more cautious use of irradiation, the incidence recently has been reduced. Pediatric thyroid carcinoma accounts for 0.5% to 3% of all pediatric malignancies (118,119). Most thyroid carcinoma patients are between 15 and 19 years of age (8). It is rare for thyroid cancer to present before age 10 years; however, it can be seen in all pediatric ages. Female to male ratio of thyroid carcinoma is 2:1 (8). Thyroid cancer usually presents with an asymptomatic, firm, and mobile midline neck mass. Over 70% have clinical, and almost 90% histologic, lymph node metastases (8). Risk of malignancy includes a history of rapid growth, new-onset hoarseness, odynophagia, hemoptysis, vocal cord paralysis, or fixation to surrounding tissues. At presentation, 8% to 22% have pulmonary metastases (120). Surprisingly, despite this advanced initial presentation, 15- to 20-year survival rates are over 90% (118,121).

As opposed to adult thyroid carcinoma, over 90% of childhood tumors are well differentiated (120). Prior radiation exposure increases the risk for thyroid malignancy with the risk peaking 10 to 20 years after exposure (8). Other risk factors include iodine deficiency, Hashimoto thyroiditis, Grave disease, Pendred or Gardner syndrome, MEN IIA and IIB, and specific oncogenes. A solitary thyroid nodule is not common in children but 10% to 24% of such are malignant (122,123). Ultrasonography differentiates cystic and solid masses. However, cystic nodules in children do not exclude malignancy (8). Recently, FNAB, with ultrasound guidance when indicated, with or without sedation, is more frequently performed in children.

The surgical approach for children remains controversial due to the desire to achieve improved disease eradication with the possibility of increased risk from total thyroidectomy versus the increased chance of residual or recurrent disease with hemithyroidectomy. Newer techniques for thyroidectomy, including microbipolar dissection, minimize potential risks of nerve injury and hypocalcemia (111). Children with thyroid nodules suspicious for malignancy are recommended to undergo ipsilateral lobectomy with frozen section. A frozen section diagnosis of well-differentiated thyroid carcinoma leads to near-total or total thyroidectomy (8). Palpable lymph nodes are addressed with a modified neck dissection. Gross extracapsular spread requires radical neck dissection (8). If the postoperative I 131 scan is positive, an ablative dose of I 131 is administered. Please refer to Chapter 133 for additional information on thyroid carcinomas.

Nasopharyngeal Carcinoma

In contrast to adults, epidermoid malignancies in the pediatric population are uncommon (4). NPC is a rare neoplasm in children, but is the most common pediatric epithelial neoplasm, occurring primarily in the adolescent age group (26). It is classified according to the WHO system into WHO I (keratinizing squamous), WHO II (nonkeratinizing squamous), and WHO III (undifferentiated). Most NPCs in children are undifferentiated (WHO III). It is associated with elevated EBV titers, suggesting an infectious etiology (26). Most children present with asymptomatic cervical lymph node metastasis. Commonly, unilateral otitis media, progressive nasal obstruction, and rhinorrhea are present. Headaches and cranial nerve palsies suggest skull base involvement. The tumor may mimic the common cold or rhinitis by presenting with nasal obstruction. Other symptoms may include epistaxis, otalgia, and conductive hearing loss. NPC may invade the skull base directly and involve cranial nerve VI, causing weakness of lateral gaze and diplopia. Other cranial nerves that can become involved include III, IV, and V, and, eventually, cranial nerves IX to XII (111). Distant metastases are common at the time of presentation. Undifferentiated NPC is radiosensitive. Adjuvant chemotherapy may improve the prognosis in some patients who have disseminated disease. Extensive surgical resection is not applicable to children due to skeletal immaturity, surgical morbidity, and concern about incomplete resection (111). Overall 5-year survival in children with NPC approaches 40%.

CONCLUSIONS

Head and neck masses in children are a common clinical concern. The differential diagnosis for a head and neck mass is broad, including congenital, inflammatory, and neoplastic lesions. A thorough examination of the head and neck and other systems with appropriate workup will narrow the differential diagnosis. The common pathologies can be differentiated with a clear understanding of embryology and anatomy of the region and knowing the natural history of the common diseases. While benign masses are much more common, care must be taken to rule out malignancy, particularly when early diagnosis and treatment leads to very high survival rates in general.

HIGHLIGHTS

- The majority of pediatric head and neck masses are congenital and inflammatory, with 80% to 90% representing benign conditions.
- Congenital masses may not be identified at birth or during infancy and may become apparent secondary to an infection later in childhood.
- The most common etiology for cervical adenopathy in children is reactive lymphadenopathy following a viral or bacterial illness.

- Adenopathy of viral etiology is usually bilateral, rarely suppurates, and generally resolves spontaneously, while bacterial adenitis is usually unilateral and develop fluctuance in 25% of cases.
- Any palpable solid mass at birth is abnormal and requires an evaluation to develop a definitive diagnosis.
- A lymph node greater than 1 cm in size in an infant younger than 1 year old is considered abnormal and a lymph node 3 cm or larger in a child older than 1 year old should be investigated.
- A rapidly enlarging, nontender, or long-standing neck mass with overlying skin changes raises the suspicion of malignancy. This suspicion is heightened when associated with fever, night sweats, and weight loss or located in the posterior triangle or supraclavicular space.
- A malignant lymph node may have metastasized from an oro-naso-hypopharyngeal primary; therefore, a thorough endoscopic examination of those sites should be performed in such cases.
- RMS is the most common soft tissue malignancy in childhood; however, diagnosis often gets delayed due to nonspecific symptoms at presentation as well as variable site presentation.
- Over 50% of pediatric neck malignancies are lymphomas (Hodgkin disease and non-Hodgkin lymphoma), which are treated with chemotherapy, and, sometimes, radiation therapy.

Congenital Cysts and Sinuses of the Head and Neck

106

Robert F. Yellon

INTRODUCTION

Embryologic developmental anomalies are fairly common in the pediatric population. Failure of involution embryologic structures and duplication of structures can lead to fistulas, sinuses, and cysts. These include first, second, third, and fourth branchial cleft anomalies (BCAs), as well as preauricular cysts and sinuses and thyroglossal duct cysts (TGDCs). A fistula has an opening from the pharynx to the skin. A sinus is an incomplete fistula and has an opening to either the pharynx or skin. A cyst is an enclosed structure with no opening to the pharynx or skin. Failure of migration or incomplete or excessive migration of embryologic structures results in ectopic structures such as lingual thyroid and ectopic thyroid. Failure of involution of the embryologic thyroglossal duct leads to formation of TGDCs anywhere along the pathway from the base of tongue, submental region, and the anterior neck. Dermoid and epidermoid cysts arise from ectodermal tissues. They represent early embryonic displacements of epithelial nests.

These congenital anomalies may remain asymptomatic, not be obvious on clinical exam, and never require any treatment. Alternatively, enlargement of the lesion may lead to concern for possible malignancy or cosmetic deformity. Mild infections, drainage, or abscess formation may also occur. Enlarging and infected lesions and lesions that interfere with normal functions are possible indications for surgical excision.

Infected cysts and sinuses may be treated with oral or intravenous antimicrobial agents. More severe infections may require needle aspiration possibly guided by ultrasound or computed tomography (CT). Failure of these lesions to respond to these interventions and severe infections and abscesses may require incision and drainage. However, incision and drainage should be used as the last resort when other lesser measures have failed. The reason for avoiding incision and drainage if possible is to avoid violation of tissue planes and violation of the walls of the congenital anomaly, which may possibly make complete excision at a later date more difficult due to scarring and unclear extent of the lesion. The definitive surgical excision may usually be delayed until 3 to 4 years of age unless the severity warrants earlier excision, which may be necessary at any age.

TGDCs are the most common congenital neck anomaly in children. For BCAs, the second BCA is most common. In a series of 97 BCAs, 18% were first BCAs, 69% were second BCAs, and 7% were third BCAs (1). Thirty-two percent of these lesions had infections previous to surgery and 71% of those had more than one infection. Fistulas and sinuses were infected more frequently (67%) than cysts (21%).

Diagnostic studies include CT with contrast, magnetic resonance imaging (MRI) with gadolinium contrast, ultrasound, and fine-needle aspiration. Of course the most definitive diagnostic test is surgical excision with pathologic examination.

There have been recent reports showing efficacy of fine-needle aspiration and sclerotherapy for selected second BCAs and TGDCs in adults with OK-432. In one series, 7/12 (58%) BCAs treated with OK-432 had complete resolution of the lesion (2). In another series, 14/23 (61%) BCAs had complete resolution of the lesion (3). Unilocular lesions had a higher success rate than multilocular lesions, which had only partial or no response to OK-432. In a third series, OK-432 was successful for resolution for 9/18 (50%) second BCAs and 5/11 (46%) TGDCs (4). Fever, pain, and odynophagia may occur following OK-432 sclerotherapy.

First Branchial Cleft Anomalies

First BCAs are not very common and are often confused with other less complex lesions. Any mass that is located near the lobule of the ear may be a first BCA. The differential diagnosis includes lymph nodes, sebaceous cysts,

dermoid cysts, lymphatic vascular malformations, and parotid and other tumors. CT and MRI are critical prior to any surgical intervention other than fine-needle aspiration. Solid lesions are likely to be lymph nodes and tumors. Multilocular lesions are likely to be lymphangiomas. Cystic lesions filled with solid rather than fluid material are likely to be dermoids. Fluid-filled cystic lesions may be simple cysts; however, it is possible that the fluid-filled cystic lesion may represent a first BCA (Fig. 106.1).

If a first BCA is suspected, and a surgery for removal is planned, the critical point to keep in mind is that there may be a deep portion of the lesion that may run medial or lateral to the main trunk of the facial nerve or between branches (5,6). If the deep portion of first BCA lesion is not removed along with the cystic portion, recurrence is likely. Since the deep tract of the first BCA runs in proximity to the facial nerve, injury of the facial nerve is possible unless the facial nerve is first identified and preserved. Then the entire first BCA lesion can be safely removed. Facial nerve monitoring and intraoperative testing are helpful for the dissection (Fig. 106.2) (Table 106.1).

Thus, it is wise to suspect that any cystic lesion in proximity to the lobule is possibly a first BCA with a deep tract extending to the facial nerve. The lesion should be approached carefully, and if a deep tract is noted, then the facial nerve is identified and preserved prior to removal of the deep tract.

First BCAs occur in two varieties as described by Work (7). A Work type 1 first BCA contains only ectoderm, often has a pit in the external auditory canal, and is considered a duplication of the external auditory canal. A Work type 2 lesion will contain derivatives of two germ cell layers, ectoderm and mesoderm.

Since the relationship of the first BCAs and the facial nerve may not be recognized, it is not uncommon for a surgeon to encounter a lesion that recurs following an inadequate resection by another surgeon. In one series of 18 first BCAs, 65% had undergone incomplete surgery prior to referral (5). The scarring resulting from the first surgery makes the dissection and preservation of the facial nerve more difficult, which may result in a very challenging surgery. Occasionally, a first BCA may present along the anterior border of the sternocleidomastoid muscle slightly lower in the neck than the inferior aspect of the lobule. It is therefore also possible to confuse a first BCA with a second BCA that usually occurs along the anterior border of the sternocleidomastoid muscle in the midneck area.

Figure 106.1 Surgical exposure of first BCA.

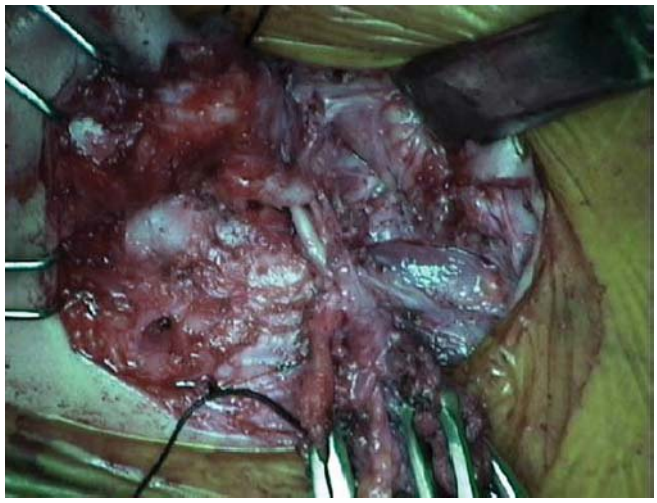

Figure 106.2 Seventh nerve dissection is required to fully and safely excise deep portion of first BCA. Note trunk of seventh nerve (*white*) with tract of first BCA adjacent to right side.

Second Branchial Cleft Anomalies

Second BCAs are the most common of the three types of branchial cleft lesions. As noted above, these lesions commonly occur along the anterior border of the

TABLE 106.1 ANATOMIC PATHWAYS FOR DEEP TRACT OF FIRST, SECOND, THIRD, AND FOURTH BCAS

- First BCA
  - The tract may run medial or lateral to the main trunk of the facial nerve or between branches.
- Second BCA
  - The deep tact runs between the internal and external carotid arteries and superior to the glossopharyngeal and hypoglossal nerves and finally ends at the tonsillar fossa.
- Third BCA
  - The deep tract passes posterior to the internal and external carotid arteries, between the 9th and 12th cranial nerves, and ends in the apex of the pyriform sinus.
- Fourth BCA
  - The deep tract begins with a sinus at the apex of the pyriform sinus and travels inferiorly in the tracheoesophageal groove, posterior to the thyroid gland, and into the thorax. Next, it loops below the aorta on the left or below the subclavian artery on the right and then ascends posterior to the common carotid artery to loop over the hypoglossal nerve and ends at the anterior border of the sternocleidomastoid muscle.

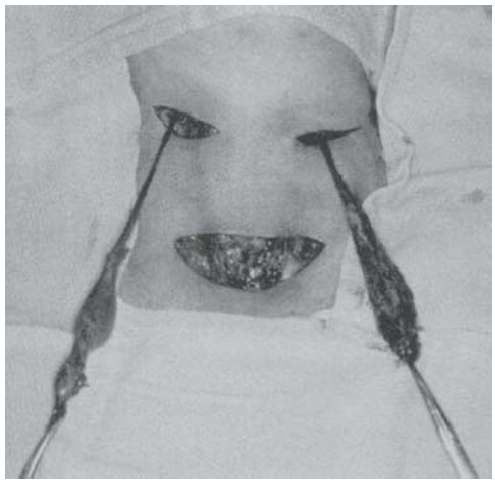

Figure 106.3 Surgical excision of bilateral second branchial cleft cysts in a child with BOR syndrome.

sternocleidomastoid muscle in the midneck region. Like the first BCAs, the second BCAs may also have a deep tract (Fig. 106.3). It is critical to understand the anatomic path of the second BCAs for safe and complete excision. The deep tact runs between the internal and external carotid arteries and superior to the glossopharyngeal and hypoglossal nerves and finally ends at the tonsillar fossa (Table 106.1).

A particular cyst or sinus may or may not have a deep extension. The surgeon must be prepared to dissect out a possible deep tract that ends at the tonsillar fossa and then tie off the tract. If the deep portion is not dissected out and excised, recurrence of the lesion is more likely. Gently placing a lacrimal probe into the skin opening of a sinus or fistula can help determine the direction and depth of the tract, which may aid dissection, but care must be taken to avoid rupturing the tract. Other surgeons prefer to inject methylene blue into the tract to aid dissection, but again rupturing the tract can lead to staining of uninvolved tissues and a more difficult dissection. If a branchial remnant is infected, intravenous antimicrobial agents should be administered. If an uninfected lesion is breached, a culture should be taken and intravenous antimicrobials should be administered. Antimicrobials are not required for clean cases with no breach of the lesion.

Although some surgeons advocate excision of the tonsil on the side of the lesion, most surgeons do not excise the tonsil and tie off the tract close to the tonsillar fossa.

Third Branchial Cleft Anomalies

The third and fourth BCAs are rare, often misdiagnosed, and thus often recurrent. The most common presentation is a cystic mass or abscess along the anterior border of the sternocleidomastoid muscle in the mid- to lower neck. Over 90% occur on the left side (8,9). These lesions are often misdiagnosed as recurrent neck abscesses or thyroid abscesses or cysts. The key to diagnosis is to understand the potential for these lesions to have a deep tract that extends

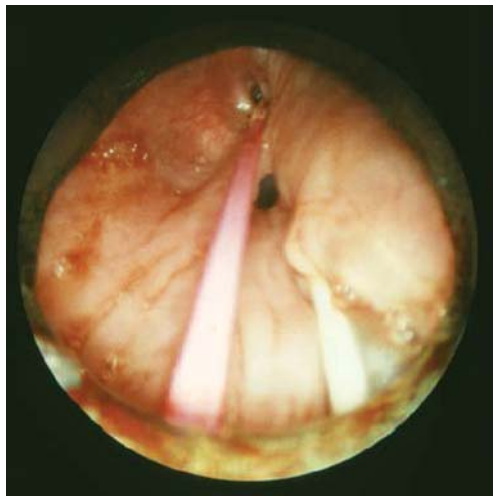

Figure 106.4 Third BCA with sinus opening into the pyriform sinus. Fogarty catheter has been placed into sinus to facilitate dissection of deep tract to pyriform sinus.

near the thyroid gland to end as a sinus in the pyriform sinus. Simple incision and drainage often leads to recurrence of the abscesses. The diagnosis is made by several means. One is a thorough pharyngoscopy at the time of incision and drainage that shows a sinus tract in the apex of the pyriform sinus (Fig. 106.4). CT scan may show an air-filled structure in the apex of the pyriform sinus or a cystic structure with a deep extension approaching the pyriform sinus (Fig. 106.5). Modified barium swallow may show a barium-filled sinus in the apex of the piriform sinus.

To properly excise the third BCAs, the anatomic course of the tract must be known. The tract of this anomaly passes posterior to the internal and external carotid arteries and between the ninth and twelfth cranial nerves and ends in the apex of the pyriform sinus (Table 106.1). A small catheter placed in the sinus opening in the apex of the pyriform sinus is helpful prior to excision since palpation of the catheter makes the tract easier to identify during excision (Figs. 106.4 and 106.6). Hemithyroidectomy may

Figure 106.5 CT of third BCA.

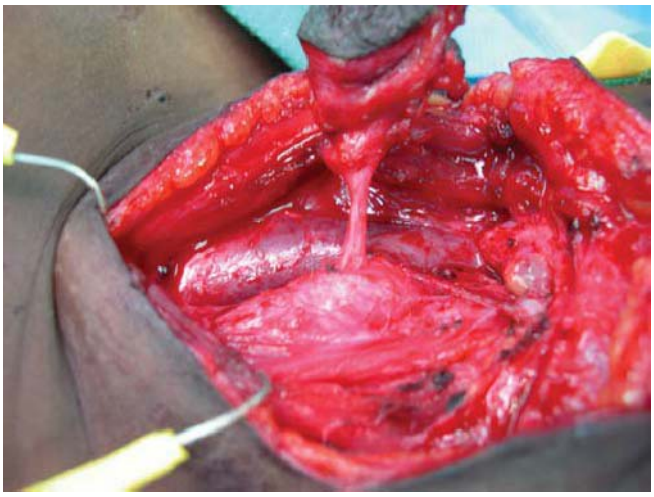

Figure 106.6 Dissection of third BCA to pyriform sinus.

be required for some third branchial cleft lesions that are intimately associated with the thyroid gland.

Some recent reports have described success in treating third and fourth BCAs by electrocautery or laser of the sinus opening in the pyriform apex (8,9). This approach may be helpful in very young or very ill children. This approach also makes the differentiation between the third and fourth BCAs irrelevant since the clinical presentation and endoscopic treatment are the same for both lesions (8).

Fourth Branchial Cleft Anomalies

The uncommon fourth BCA also has a sinus opening into the pyriform sinus; however, the anatomic pathway differs from that of the third BCA. Indeed, it is often impossible to discern whether a particular anomaly is a third or fourth BCA without surgical dissection. Over 90% occur on the left side (8,9). The diagnosis of a fourth BCA may be made by the following methods. These are the same methods used to identify the third BCAs. Thorough pharyngoscopy at the time of incision and drainage will show a sinus tract in the apex of the pyriform sinus. CT scan may show an air-filled structure in the apex of the pyriform sinus. Modified barium swallow may show a barium-filled sinus in the apex of the pyriform sinus. Similar to the third BCAs, the fourth BCAs are often misdiagnosed as neck abscesses or recurrent thyroiditis.

The anatomic pathway of the tract of a fourth BCA begins with a sinus at the apex of the pyriform sinus and travels inferiorly in the tracheoesophageal groove, posterior to the thyroid gland, and into the thorax. Next, it loops below the aorta on the left and below the subclavian artery on the right and then ascends posterior to the common carotid artery to loop over the hypoglossal nerve and ends at the anterior border of the sternocleidomastoid muscle (9) (Table 106.1).

In one series, 19/20 third and fourth BCAs in children were treated with endoscopic electrocautery or laser for ablation of the sinus opening in the pyriform sinus (8). Thirteen of nineteen (68%) were successful with a single procedure, 78% were successful with 2 procedures, and 89% were successful with 3 procedures. In two of five neonatal cases, open surgical excision was required to relieve severe airway obstruction, one after failed endoscopic treatment.

PREAURICULAR CYSTS AND SINUSES

Embryologically, the six hillocks of His, derived from the first and second branchial arches, fuse to form the auricle. A preauricular cyst or sinus arises from partial failure of involution of the epithelium between the first and second hillocks. These common congenital lesions usually have a punctum anterior to the root of the helix (Fig. 106.7), a short tract, and a sinus, which ends with an attachment to the perichondrium of the root of the helix.

These lesions often remain asymptomatic. However, it is not uncommon for these lesions to leak a small amount of mucoid discharge, or to get infected. Treatment of infected preauricular sinuses includes oral antimicrobials, but needle aspiration or incision and drainage may be required for some infections/abscesses. Avoidance of incision and drainage is preferable if possible since violation of the sinus may make definitive surgical excision more difficult due to scarring and less clear tissue planes.

A period of approximately 6 weeks is allowed following infection of preauricular sinuses to allow for resolution of inflammation. Surgical excision then can begin with gentle

Figure 106.7 Preauricular sinus.

insertion of a small lacrimal probe into the punctum to identify the direction of the sinus cavity, which almost always goes to the perichondrium of the root of the helix. The punctum should be excised using an elliptical incision. The tract and then sinus are then traced to the perichondrium of the root of the helix. The perichondrium is scored sharply and peeled off the cartilage of the root of the helix (Fig. 106.8). Any associated scar tissue or granulation tissue is excised along with the lesion. There is no concern for injury to the facial nerve during dissection in the preauricular area. The facial nerve is deeper and inferior to the area of dissection.

It is not uncommon to see patients with recurrence of preauricular cysts or sinuses following surgery. A portion of the sinus may have been left in situ following surgery complicated by scar, inflammation, or granulation tissue. It is very common that the attachment of the sinus to the root of the helix was left behind, and this is the focus of the recurrent infection. For revision cases with abscess or inflammation adjacent to the root of the helix, it is difficult to peel the perichondrium in this area off the helical cartilage. It is therefore recommended that the full thickness of cartilage is excised to assure complete removal.

Occasionally, a surgeon encounters a case of infected preauricular sinus that has undergone multiple prior attempts at excision. For such cases, a block dissection is performed in the preauricular area with excision of all the inflamed and scarred tissue down to the preauricular/parotid fascia (Fig. 106.9). As described above, the area of the cartilage of the root of the helix must be addressed. Again, the facial nerve is not at risk since the nerve is deep to the fascia and inferior to the area of dissection. Local cheek advancement flaps are usually sufficient to allow closure of the wound. Rarely a superiorly pedicled postauricular skin flap is rotated to fill the defect in the preauricular area.

Figure 106.8 Dissection of preauricular sinus down to perichondrium of root of helix. It is important to excise this perichondrium to assure complete excision.

Figure 106.9 Recurrence of infected preauricular sinus requiring block dissection down to fascia.

BRANCHIOOTORENAL (MELNICK-FRASER) SYNDROME

Patients with a combination of bilateral preauricular sinuses, bilateral second or third BCAs in the neck, and renal disease most likely have branchiootorenal (BOR) syndrome (Fig. 106.3) (10). This is an autosomal dominant genetic syndrome with variable penetrance. It can be detected prenatally with genetic testing. Hearing loss may be conductive or sensorineural. The auricle may be normal, slightly anomalous, or microtia may be present. The kidneys may be normal, anomalous but functioning, or absent (Table 106.2).

If a child is found to have only bilateral preauricular sinuses, the chance of hearing loss is 1 in 200. If a child is found to have bilateral preauricular sinuses and bilateral

TABLE 106.2 CLINICAL FINDINGS IN BOR (MELNICK FRASER) SYNDROME (10)

- Hearing loss
- Preauricular pits
- Branchial fistulas or cysts
- Anomalous pinna
- Renal dysplasia

BCAs in the neck, the chances of hearing loss are much higher and renal studies are indicated. Family members should also be examined and tested, when appropriate.

THYROGLOSSAL DUCT CYSTS

The embryonic thyroid gland arises at the foramen cecum at the junction of the anterior two-thirds and posterior one-third of the tongue. The gland then usually passes inferiorly through the base of tongue. Next, it passes anterior or posterior to the center of the hyoid bone. It then continues to migrate inferiorly into the lower neck to its final location. This embryologic path of the thyroid gland is known as the thyroglossal duct. Failure of involution of a portion of the thyroglossal duct results in a TGDC.

A TGDC may be small and remain occult. Alternatively, it may be discovered on routine physical exam. Other presentations include slow enlargement of a midline neck mass, or infection of the mass with rapid enlargement (Fig. 106.10). Children with TGDCs are usually euthyroid. However, if hypothyroidism is suspected, thyroid function tests should be obtained with endocrinology consultation when indicated.

The differential diagnosis of a midline neck mass includes TGDC, dermoid cyst, and lymph node. Ultrasound or CT is useful to determine whether the mass is solid or cystic. Obviously solid lesions are more likely to be lymph nodes and cystic lesions are more likely to be TGDCs or dermoids. Fluid-filled TGDCs often have a lower density center compared to dermoid cysts, which are usually filled with thick cheesy material. The presence of the normal thyroid gland in the normal location is also important to evaluate on the ultrasound or CT exam to know that the mass in question is not in fact ectopic thyroid gland. Ultrasound has the advantage of no radiation exposure compared to CT scan.

Excision of TGDCs is usually recommended. This is recommended to confirm the diagnosis, prevent recurrent infections, and to be certain that the lesion does not contain thyroid cancer. The standard surgery for TGDCs was described by Walter Sistrunk in 1920 (11). Sistrunk understood the embryologic pathway of the thyroid gland and TGDC and incorporated it into the definitive surgery he described. The "Sistrunk procedure" includes resection of the cystic mass, the associated deep tract, the middle third of the hyoid bone, and a portion of the base of tongue deep to the foramen cecum. When this method of excision is used, the chance of recurrence of the lesion is reduced compared to simple excision of the cyst (Figs. 106.11 and 106.12). At the Toronto Hospital for Sick Children, they reviewed 143 patients with TGDCs that underwent 214 surgical procedures. One hundred five patients needed only one operation. Thirty-eight had recurrent disease and needed 109 procedures for cure. Inadequate surgery was the direct cause of recurrence. The authors had a 6.5% recurrence rate using the Sistrunk procedure versus general surgeons who did less and had a 23% recurrence rate (12).

Postsurgical recurrence of the TGDCs may still occur especially when there has been inaccurate initial diagnosis, previous infection, incision and drainage with scarring and distortion of tissue planes, unusual presentations (lateral neck, base of tongue), or lack of base of tongue muscle removal (13). Since the tract of a TGDC may pass posterior to the hyoid bone, dissection of the hyoid bone

Figure 106.10 Typical TGDC in midline of neck.

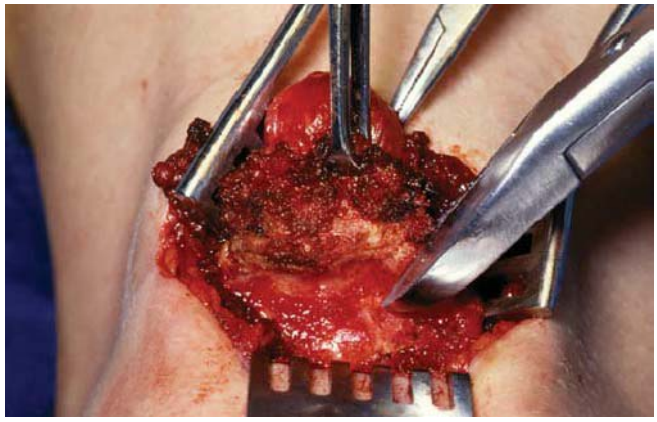

Figure 106.11 Sistrunk procedure. The TGDC has been mobilized, and the central portion of the hyoid bone is being transected with a rongeur.

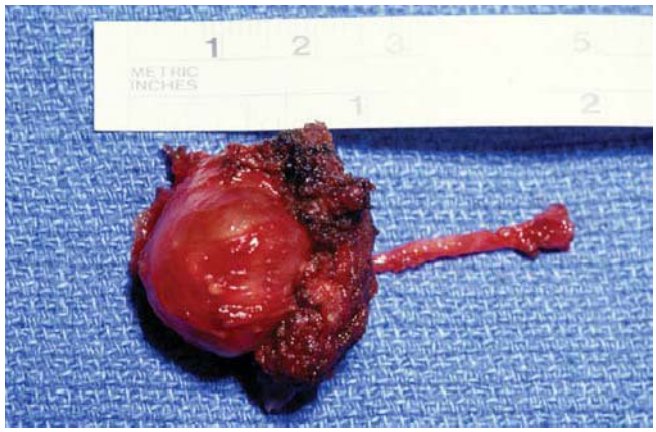

Figure 106.12 Specimen following Sistrunk procedure with TGDC, central portion of hyoid bone, and tract from base of tongue.

and "posterior hyoid space" has been recommended with removal of all tissue posterior to the middle portion of the hyoid bone and anterior to the thyrohyoid membrane to decrease recurrence (14).

For recurrent cases of TGDC, the so-called central compartment neck dissection is performed (Fig. 106.13). This procedure would include all aspects of the standard Sistrunk procedure plus excision of all tissue between the skin and fascia over the strap muscles and mylohyoid muscles that occurs medial to the sternocleidomastoid muscles and the digastric muscles. Any skin that is adherent to the mass is excised as well.

Suture-guided transhyoid pharyngotomy was described as a helpful procedure to address recurrent TGDCs (13). In this procedure, a 20-gauge spinal needle is passed through the area of recurrent TGDC in the neck to the foramen cecum of the tongue. A heavy permanent suture is passed through the spinal needle and retrieved via the oral cavity. The spinal needle is removed. A portion of a red rubber catheter is tied to the oral side of the suture. The central compartment neck dissection and the revision Sistrunk procedure are then performed. After the central portion of the hyoid bone is excised, the suture and red rubber catheter are pulled for traction to allow excision of the base of tongue musculature and foramen cecum to remove thyroglossal duct remnants. The foramen cecum is then closed with eversion of the mucosal edges. The success rate was 8/8 (100%) for this revision procedure.

Figure 106.13 Recurrent infected TGDC that will require central compartment neck dissection and revision Sistrunk procedure.

Lingual TGDCs may be discovered incidentally or may be associated with life-threatening airway obstruction. Microsuspension laryngoscopy with endotracheal intubation has been reported to be successful for management of these cases using electrocautery, cold dissection, and microdebrider (15).

Antimicrobials are not usually administered unless the lesion is obviously infected. Cultures should be obtained prior to antimicrobial administration in such cases. If a lesion is ruptured intraoperatively, or the pharynx is entered, the wound is closed, cultures are taken, and antimicrobials are administered. If the pharynx is inadvertently entered, the mucosa is closed and a feeding tube is placed. Inadvertent entry into the pharynx is more likely to occur during revision cases or cases associated with multiple infections when excessive scarring and anatomic distortion are present. A radiographic contrast swallowing study is obtained after 3 to 5 days to assure closure prior resumption of oral feeding. In contrast to adult cancer patients with such injuries, children heal rapidly as there is no cancer or radiation to impair healing.

The chance of a TGDC containing cancer is only about one in one hundred. These are usually discovered inadvertently at surgery. The distribution of thyroid malignancies found mirrors the distribution of malignancies seen in the main thyroid gland with papillary (16) and follicular types as the most common. The criteria for diagnosis of thyroid carcinoma arising in TGDC include a thyroglossal remnant that can be distinguished from a cystic lymph node metastasis and a normal thyroid gland (17). When thyroid cancer is found in association with a TGDC, thyroid nuclear medicine scan is advised. Further surgery is contraindicated if the thyroid scan is normal. The patient should be referred to a surgeon specializing in head and neck oncology. I^{131} scan is indicated to prove the thyroid gland is present and to rule out other tumors in the gland. Total thyroidectomy is performed if additional tumor is found. I^{131} scan is performed after surgery if differentiated cancer is diagnosed. Synthroid is administered for replacement and suppression of thyroid-stimulating hormone.

ECTOPIC THYROID AND LINGUAL THYROID

As discussed above in the section on TGDCs, the thyroid gland anlaga begins at the foramen cecum at the junction of the anterior one-third and posterior two-thirds of

the tongue. It then passes inferiorly through the base of tongue and then passes anterior or posterior to the central portion of the hyoid bone. Next, the descent continues to the lower central neck. Ectopic thyroid may occur at any location along the embryologic pathway of descent when migration is arrested. The ectopic tissue may be at the base of tongue (90%), within the tongue, submental area, and anterior aspect of neck. Additional rare sites for ectopic thyroid include trachea and mediastinum. Cases of dual ectopic thyroid have been reported with more than one focus of ectopic thyroid (18). Hypothyroidism associated with ectopic thyroid is not uncommon and thyroid function tests are indicated.

Ectopic thyroid that remains at the base of tongue is referred to as "lingual thyroid." Lingual thyroid occurs in 1:100,000 people. Female to male ratio is 4:1. Seventy to one hundred percent of those affected have no other thyroid tissue, and 14% to 33% of patients with lingual thyroid are clinically hypothyroid.

The majority of excised lingual thyroids reveal histologically normal thyroid tissue. Lingual thyroid may cause dysphagia, dysphonia, airway obstruction, or bleeding. Lingual and ectopic thyroid when symptomatic may require treatment. Endocrinology consultation for thyroid suppression may be helpful for milder cases. Severe cases with airway obstruction or bleeding may require surgical excision via a transoral approach, transhyoid pharyngotomy, lateral pharyngotomy, or rarely midline labiomandibulotomy. It is helpful to place sutures around the lingual thyroid tissue prior to excision that are left long and then tied after the mass is excised to decrease blood loss. Autotransplantation of excised ectopic thyroid is not advised due to the small chance of the presence of thyroid carcinoma (19).

DERMOID CYSTS

Epidermoids contain only epidermal tissue, while dermoids may also contain hair follicles and sebaceous glands. Epidermoid and dermoid cysts of the head and neck usually occur in the so-called T distribution involving the midline of the face and anterior neck and the orbits and periauricular area. When a round mass occurs in the anterior neck of a child, the differential diagnosis includes TGDC, dermoid, and lymph node (Fig. 106.14). On CT or ultrasound examination, a TGDC will usually have a cystic appearance and low-density, fluid-filled contents, while the dermoid will have cystic appearance but a more dense center. The lymph node will have a solid tissue density center.

Dermoids may occur in the region of the nasal dorsum. The primitive frontonasal region or anterior neuropore develops medial to the optic recesses in the third week of fetal life. Through the 8 weeks, a transient fontanelle called the foramen cecum is present between the inferior frontal bone and nasal bone. A dural projection extends inferiorly through the opening anterior to the crista galli of the ethmoid bone. The apex of the dural projection approximates the subcutaneous region posterior to the frontal and nasal bones and anterior to the nasal cartilage. Failure of involution of these structures results in dermoid, glioma, and encephalocele (20).

Figure 106.14 Specimen of midline neck mass. The mass was originally approached as a TGDC with a Sistrunk procedure, but when hair was seen coming from the mass, it was clearly a dermoid cyst and simple excision was performed.

Thus, when a cystic-appearing mass occurs in the dorsum of the nose or in the intranasal region in a child, the differential diagnosis includes dermoid (Fig. 106.15), glioma, and encephalocele. Since the mass may have an intracranial extension, biopsy or excision of the mass without CT and possibly MRI is to be condemned as it may cause cerebrospinal fluid leak and meningitis. Gliomas are heterotopic brain tissue. For nasal dermoids or gliomas without intracranial extension, open rhinoplasty approach or direct incision over the mass (Fig. 106.16) is adequate. Endoscopic-assisted, closed rhinoplasty approaches have been recently described (21). Nasal bone osteotomy may be necessary for adequate exposure, and permanent nasal deformity is not uncommon. It is wise to advise the parents of the possibility of significant nasal deformity and

Figure 106.15 Dermoid sinus with pit splaying apart the nasal bones.

that secondary rhinoplasty may be required when the child is older.

If intracranial extension of the mass is detected on CT or MRI, consultation from neurosurgery (22) or surgeons specializing in the extended endonasal endoscopic approach is required (23).

ACKNOWLEDGMENT

The author would like to acknowledge Dr. Eugene Myers for providing several excellent photographs.

HIGHLIGHTS

- Infected congenital cysts and sinuses and BCAs may be treated with antimicrobial agents and possibly needle aspiration. Incision and drainage should be avoided if possible since scarring may make excision more difficult.
- Recent reports have shown some efficacy of fine-needle aspiration and sclerotherapy for selected second BCAs and TGDCs with OK-432.
- It is wise to suspect that any cystic lesion in proximity to the lobule is possibly a first BCA with a deep tract extending to the facial nerve. The lesion should be approached carefully, and if a deep tract is noted, the facial nerve is identified and preserved.
- Second BCAs, the most common of the BCAs, occur along the anterior border of the sternocleidomastoid muscle in the midneck. Second BCAs may have a deep tract that runs between the internal and external carotid arteries and superior to the glossopharyngeal and hypoglossal nerves and ends at the tonsillar fossa.
- Third BCAs are rare, often misdiagnosed, and often recurrent. Over 90% occur on the left. These lesions often present as recurrent neck or thyroid abscesses or cysts. The tract passes posterior to the internal and external carotid arteries, between the ninth and twelfth cranial nerves, and ends in the pyriform sinus. Hemithyroidectomy may be required.
- The rare fourth BCA also has a sinus opening into the pyriform sinus. Over 90% occur on the left. The tract begins with a sinus opening in the pyriform sinus, takes an intrathoracic path, and then ends at the anterior border of the sternocleidomastoid muscle.
- Third and fourth BCAs may be selectively treated with electrocautery or laser ablation of the sinus in the pyriform sinus. Surgical excision is required for airway obstruction.
- When excision is necessary for preauricular sinuses, the tract and sinus are traced to the perichondrium of the root of the helix, which is scored sharply and peeled off the cartilage. It is common to see patients with recurrence when perichondrium was not excised. Full thickness of cartilage is then excised to assure removal.
- Patients with a combination of bilateral preauricular sinuses, bilateral second or third BCAs in the neck, and renal disease most likely have BOR syndrome. This is an autosomal dominant genetic syndrome.

- TGDCs are the most common congenital neck anomaly. Definitive surgery is called the "Sistrunk procedure," which includes resection of the mass, the deep tract, the middle third of the hyoid bone, and a portion of tongue base.
- Ectopic thyroid may occur at the base of tongue (90%), within the tongue, submental area, anterior neck, intratracheal, or mediastinum, and is often the only thyroid tissue. Hypothyroidism is common and endocrinology consultation is helpful. Severe cases with airway obstruction or bleeding require surgical excision.
- The differential diagnosis of a mass in the dorsum of the nose or intranasal region includes dermoid, glioma, and encephalocele. There may be intracranial extension, and biopsy without CT or MRI may cause cerebrospinal fluid leak and meningitis.

The Syndromal Child

107

Ted L. Tewfik

Congenital anomalies are involved in about half of all pediatric hospital admissions and next to accidents constitute the leading cause of death in children. They involve all medical branches, cross all human medical disciplines, and present worldwide challenges. The significance of these birth defects and the accurate diagnosis of each condition or of complex syndromes are often difficult to determine.

The goal of any dysmorphic assessment is to interpret the pattern of structural anomalies correctly and arrive at the diagnosis. The practicing specialist dealing with the ear, nose, and buccopharyngeal region is confronted frequently with problems related to congenital anomalies. The spectacular advances in basic and clinical genetics during the past three decades have brought congenital malformations and inherited disorders to the forefront of medical attention and care. Congenital anomalies affect 3% of neonates; by age 5 years, as more subtle anomalies manifest, the percentage climbs from 7% to 10%. The shared spectra of dysmorphic phenotypes and their inherent variability can be overwhelming. Several thousand distinct syndromic entities have been described, and because of their rarity, the typical specialist will not encounter the vast majority of them. The purpose of this chapter is to provide the otolaryngologist with a systematic approach to the dysmorphic neonate, infant, or child and to demonstrate that dysmorphology is a learned discipline that can be practiced by any physician who is inquisitive, thorough, and willing to cultivate his or her powers of observation.

Inheritance of traits and disorders may be monogenic or multigenic or the result of the transmission of an abnormal chromosome (e.g., a deletion or a duplication). The expression of specific genes is influenced by other genes or environmental conditions. Besides the classical mendelian patterns of inheritance, several nonclassical patterns of inheritance have been discovered and studied in recent years.

Single genes are usually inherited according to one of the following mendelian patterns: autosomal dominant (AD), autosomal recessive, X-linked dominant, and X-linked recessive. These patterns may be apparent in pedigrees, the proper drawing of which is the first step in the study of inherited diseases in families. They should be included in all case histories in which a familial disease is suspected. They are also essential for linkage studies, gene mapping, genetic counseling, and prenatal diagnosis. The symbols commonly used are standard and generally accepted (Figs. 107.1 to 107.3).

A person is homozygous for a certain gene when both alleles at the same locus are identical. Heterozygosity implies the presence of two different alleles. Usually the term is used for situations when one of the alleles bears a pathogenic mutation.

There is no absolute distinction between "dominant" and "recessive" genes. By definition, a "recessive" gene has no detectable expression in a heterozygote under the conditions of study and analysis. Diseases resulting from deficiency of enzymatic activity behave as recessives because, in the heterozygous situation, the amount of enzymatic activity produced by the unaffected allele allows a normal metabolic function. When the gene codes for an abnormal structural protein, the mutant allele usually acts as a dominant. In that case, the cells of the heterozygote carry the mutant gene and synthesize a mixture of the structurally normal and abnormal proteins. As a result of changes in the physical properties of the protein, heterozygotes may show phenotypic abnormalities (1,2).

The following are the characteristics of AD inheritance:

1. At least one of the parents of an affected person is also affected, except when the penetrance is reduced or the trait arises by a new mutation or when there is germline mosaicism. The trait appears in every generation. There is no "skipping" except when the "penetrance" is reduced.

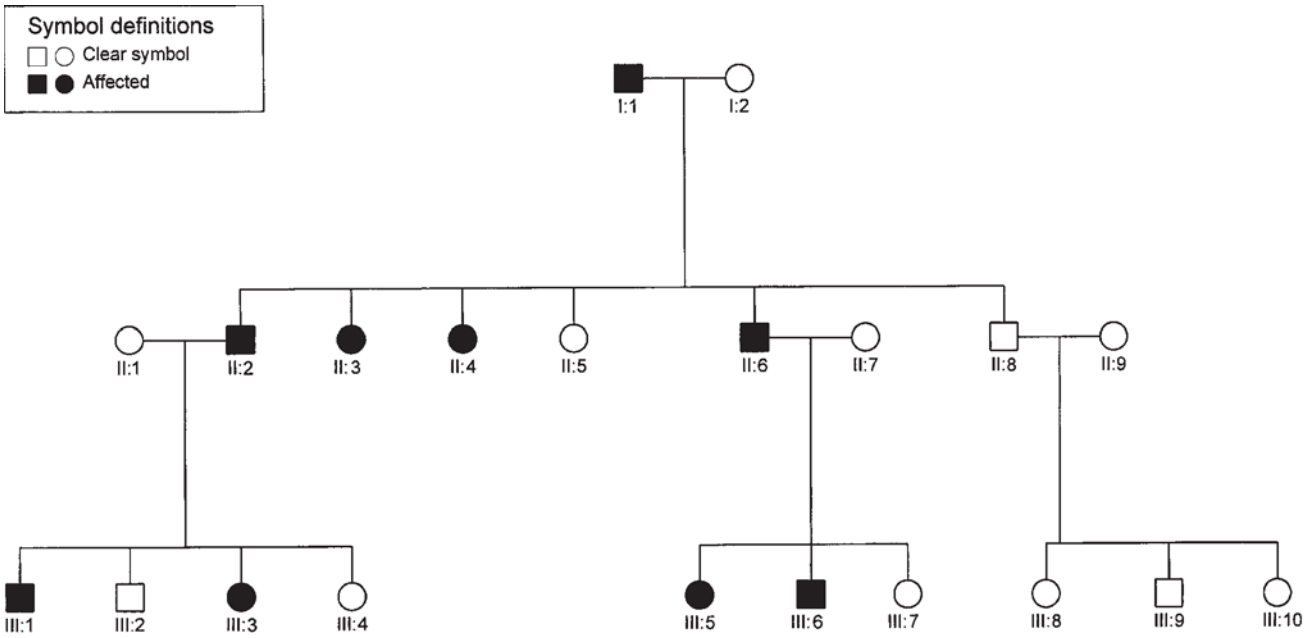

Figure 107.1 Autosomal dominant inheritance. Vertical pattern of trait expression; males and females are equally affected.

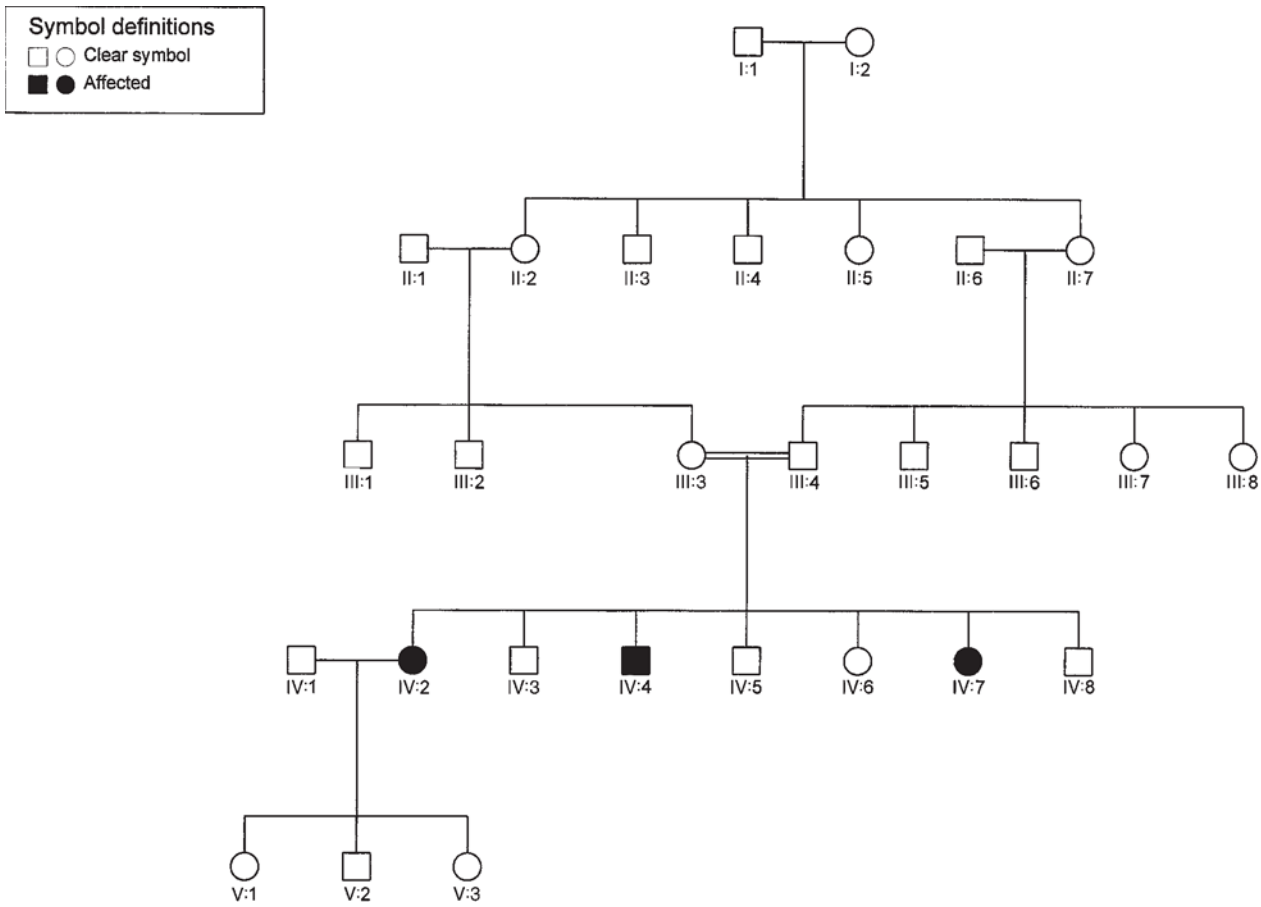

Figure 107.2 Autosomal recessive inheritance. Horizontal pattern of trait expression. Parental consanguinity is often present in families with autosomal recessive disorders.

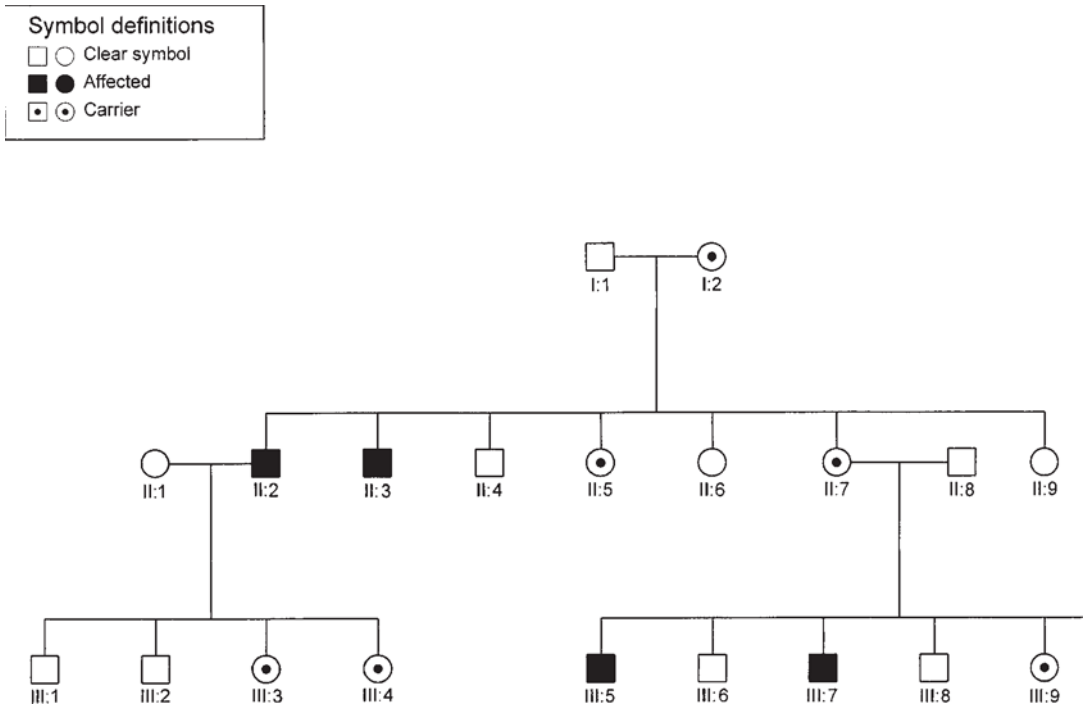

Figure 107.3 X-linked recessive inheritance. Males only are affected. There is no male-to-male transmission, and daughters of affected males are carriers.

2. An affected person heterozygous for the trait has an equal chance of transmitting the mutant or the normal allele to each child.
3. Males and females can have and transmit the trait equally.

Two traits are said to be codominant when their genes are allelic and are both expressed in a heterozygote individual. For example, in a person with blood group AB, genes for both groups A and B are expressed.

The following are the characteristics of autosomal recessive inheritance:

1. The parents are heterozygous and phenotypically normal; the trait appears only in the children who are homozygous for the mutant gene.
2. Statistically, one-fourth of the children of heterozygous parents are affected and thus there is a chance of 25% at each pregnancy.
3. Males and females have equal chance of being affected.

When an individual carries two different mutated alleles at the same locus, the condition is called a genetic compound. In consanguineous marriages, both partners have a higher risk of being carriers of the same rare recessive gene. Thus, the children who are products of consanguineous marriages run an increased risk of being affected with autosomal recessively inherited conditions. This risk may be increased by 100-fold. However, in absolute terms, it is of the order of 1%.

X-linked recessive inheritance occurs when the mutant gene is on the X chromosome. It has the following characteristics:

1. The trait is much more common in males than in females. Females have two X chromosomes, and males have only one. All males carrying the X-linked gene express the trait. Females are affected when they are homozygous and in certain rare heterozygous cases, as an effect of the Lyon hypothesis, when a high percentage of cells have random inactivation of the X chromosome carrying the normal allele.
2. An affected man passes his X-linked gene to all of his daughters who thus become carriers but are not affected. He does not transmit it to any of his sons.
3. A carrier woman passes her X-linked gene to half of her sons who manifest the trait and to half of her daughters who become carriers.

X-linked dominant inheritance has the following characteristics:

1. Affected men transmit the trait to all their daughters who then display the clinical manifestations of that particular condition. They transmit the gene to none of their sons.
2. Heterozygous women are affected. They transmit the trait to half of their sons and half of their daughters.

Y-linked genes occur only in males. They are transmitted to all the sons and none of the daughters. There are very few genes known to be definitely on the Y chromosome.

PENETRANCE

Certain traits may be modified by other genes and by environmental factors to such an extent that they may not be recognizable either clinically or by laboratory tests, although the gene causing the trait is present. In such cases, the gene or trait is said to have incomplete or reduced penetrance. Thus, certain AD traits with reduced penetrance may "skip" a generation.

EXPRESSIVITY

Expressivity indicates the variation in expression of a phenotype that a gene may have. In clinical medicine, a certain gene with variable expressivity may produce mild, moderate, or severe disease. A *forme fruste* is an extremely mild and clinically insignificant expression of a condition. Variable expressivity and *formes frustes* are noted especially in AD inheritance. For example, certain patients with cleidocranial dysostosis may not be identified clinically and are diagnosed in retrospect by special radiographic testing when other more affected members of their families are detected.

PLEIOTROPY

Pleiotropy is the occurrence of multiple phenotypic effects of a mutant gene or gene pair. For example, the primary defect in Hurler syndrome is the specific deficiency of α-L-iduronidase, with accumulation of the substrate in the lysosome. Secondary effects are mental retardation, craniofacial anomalies, dysostosis multiplex, corneal opacification, and hepatosplenomegaly.

HETEROGENEITY

A condition is causally heterogeneous when multiple causes result in the same effect. Genetic heterogeneity of a disease may result in confusing pedigrees. Thus, inherited congenital neurosensory deafness in different families may be the result of two autosomal recessive genes at two different loci. The children of two deaf individuals, each homozygous for a recessive trait at a different locus, may all have normal hearing because they will be heterozygous for two separate loci.

The craniosynostoses are also genetically heterogeneous. Thus, Pfeiffer syndrome may be the result of mutations of FGFR1 (fibroblast growth factor receptor 1) on chromosome 8 (8p11.2-p12) or FGFR2 on chromosome 10 (10q25.3-q26).

Moreover, many malformations are pathogenetically heterogeneous, separate mechanisms being responsible for the same effect. Robin sequence is an example. It is commonly present in Stickler syndrome, which is a single-gene, AD condition. Alternatively, it may be the result of predominantly environmental conditions *in utero*, such as oligohydramnios, in which case the chin is compressed against the sternum, thus restricting mandibular growth and impacting the tongue between the palatal shelves (3).

MALFORMATION

A malformation by definition is a structural morphologic defect of an organ, part of an organ, or a larger region of the body resulting from a developmental process that is intrinsically abnormal.

A major malformation is one that requires intervention, represents a significant medical or psychologic challenge, and may seriously impair or prevent normal functioning. Examples are ambiguous genitalia and anencephaly. A minor malformation is one that does not represent a lifelong medical or psychologic challenge. Such anomalies can be corrected (unilateral cleft lip, postaxial polydactyly). Minor malformations and variants are important flags for the dysmorphologist. One or two may be found in otherwise normal individuals, but the simultaneous finding of three or more minor anomalies has special significance. In such a patient, the clinician should be prompted to search for occult major malformations and consider a syndromic diagnosis.

Some hereditary traits are transmitted in a nonmendelian pattern, and they cannot be classified as AD, recessive, or X-linked. Mosaicism, uniparental disomy, genomic imprinting, and mitochondrial inheritance are examples that are not discussed here.

SYNDROME

The term *syndrome* is used to describe a broader error of morphogenesis in which the simultaneous presence of more than one malformation is known or assumed to be the result of a single etiology.

DEFORMATION

Abnormalities in form, shape, or position resulting from normal responses of the affected tissues to the presence of nondisruptive mechanical forces are known as deformations. Potter sequence is an example of deformation.

DISRUPTION

Disruption is when an originally normal developmental sequence is the victim of a process causing ischemia, tissue breakdown, or both.

The most commonly observed disruption is the result of early amnion rupture when entanglement of the fetus in free-floating amniotic bands produces partial or complete amputation of normally formed structures such as digits, limbs, or bizarre facial clefts (3).

SEQUENCE

The term *sequence* is used to designate a series of anomalies resulting from a cascade of events initiated by a single malformation, deformation, or disruption.

ASSOCIATION

An association is the nonrandom occurrence in two or more individuals of multiple anomalies not known to represent a polytopic field defect, sequence, or syndrome.

A PRACTICAL APPROACH TO THE INFANT OR CHILD WHO IS SYNDROMIC

Given the fact that several thousand distinct syndromic entities have been described, one cannot possibly successfully use a vague memorization strategy in dysmorphology. Instead, what is necessary is a systematic approach that concentrates on meticulous attention to the details of history and physical examination, combined with a method that allows the physician to sift through these details and come up with the best "clues."

History

The elements of the dysmorphologic history are identical to those of a general pediatric history, but the physician must be particularly tenacious in obtaining specific details. Keep in mind that the parents of a newborn with congenital anomalies may be unable to provide a complete and coherent account of events during the pregnancy and labor and may not have been fully aware of the nature or extent of abnormal ultrasound findings.

If you are assessing an older child, the parents may not recall many obstetric details or they may inadvertently overemphasize the importance of particular prenatal or peripartum events in an effort to explain their child's difficulties. When possible, it is always best to obtain the relevant medical records.

Physical Examination

The dysmorphology examination differs significantly from a general pediatric examination in its emphasis and attention to detail. The sequence of the examination varies with the examiner, but it should be systematic to prevent omissions.

Precise measurements with comparisons made to standardized curves are helpful in defining the problem. The most useful clues are often the most subtle. A single minor anomaly can be found in up to 30% of newborns. However, less than 10% of neonates have two or more minor anomalies, and only 4% have three or more. The presence of three unrelated minor anomalies is associated with a 20% risk of major structural defects, and most of these infants will, in fact, have a dysmorphic syndrome.

It may be necessary to examine family members, particularly for the presence of minor variants detected in the proband. Examination of the family members may also help you decide whether a mildly dysmorphic facial feature is really only a familial trait. Most parents will be happy to provide you with access to the family photo album, from which age-appropriate comparisons with your patient can be made.

Interpreting the Findings

Having identified the pertinent elements of your patient's history and physical examination, the next step is to interpret your findings from a developmental and morphologic viewpoint.

Genetic counseling is based on averaged data pooled from the general population. Information should be presented to the parents ensuring that they understand the different issues related to recurrent risks, inheritance, and prognosis.

In summary, the spectrum of dysmorphic phenotypes is broad and includes malformations, deformations, disruptions, sequences, associations, and syndromes. An effective assessment involves a meticulous history and physical examination combined with a developmental and morphologic interpretation of the findings. Additional clues are provided by ancillary investigations and the use of computer databases and literature searches. In attempting to serve the patient and family, our efforts to identify, categorize, and rationalize the abnormal will continue to provide exciting revelations into normal processes of human development. Ultimately our understanding of these processes will be greatly enhanced by rapidly advancing deoxyribonucleic acid technology. A valuable tool accessible on the World Wide Web is Online Mendelian Inheritance in Man (www3.ncbi.nlm.nih.gov/omim/). Other databases include the London Dysmorphology Database and POSSUM.

Many classifications for the congenital syndromes have been attempted; we found that the following are more inclusive. We present two classifications: one based on system involvement and the other based on etiology. A few examples are included under the different headings.

I. Classification of Otolaryngologic Syndromes and Conditions (based on system involvement)

1. Syndromes associated with ocular disease
   Usher, Norrie, Fraser, Alstrom, Bardet-Biedl
2. Syndromes associated with craniofacial anomalies
   a. Craniosynostosis
   Apert, Crouzon, Pfeiffer, Saethre-Chotzen, Jackson-Weiss, Carpenter, Antley-Bixler
   b. Abnormal contour
   Encephalocele (with absent corpus callosum, clefting, Dandy-Walker and Arnold-Chiari malformations, ectrodactyly, hypothalamic pituitary dysfunction)
   c. Orofacial clefting

Facial clefts and associated anomalies, Tessier clefting system, lateral facial clefts, oblique facial clefts, median mandibular defects
d. Branchial arches
Goldenhar, Treacher Collins, Nager, Miller, Wildervanck, Möbius, oro-facial-digital syndromes (I–VIII)
e. Unusual facies
Opitz BBB/G, Noonan, Robinow, Binder, Coffin-Siris syndromes
3. Syndromes associated with nervous system disease
Neurofibromatoses (1–8), Melkersson-Rosenthal, Cockayne, Friedreich ataxia, Hallgren, Prader-Willi
4. Syndromes associated with integumentary system disease Waardenburg, Leopard
5. Syndromes associated with musculoskeletal anomalies ichthyosis syndromes (Desmons, KID), oculocutaneous albinism syndromes, Ehler-Danlos syndromes
a. With contractures
Multiple pterygium, Whistling face, Schwartz-Jampel, Marden-Walker
b. Abnormal stature
i. Short
Aarskog, Cornelia de Lange, Hallerman-Streif, Rubinstein-Taybi, Silver-Russell, Bloom, Seckel
ii. Moderate
Smith-Lemli-Opitz
iii. Overgrowth
Sotos, Marshall-Smith, Weaver, Beckwith-Wiedeman
iv. Senile appearance
Progeria
c. Osteochondrodysplasia
Achondrogenesis (types I–IV), achondroplasia, campomelic dysplasia, chondrodysplasia punctata, Kniest, Nance-Sweeney, osteogenesis imperfecta (OI) (types I–IV)
d. Other skeletal disorders
Craniometaphyseal dysplasia, Van Buchem disease, sclerosteosis, Camurati-Engelmann disease, cleidocranial dysplasia, Marfan syndrome, McCune-Albright, Stickler
6. Syndromes with urogenital anomalies
Branchio-oto-renal (BOR), Alport, Renal tubular acidosis
7. Syndromes with metabolic (and endocrine) anomalies
Mucopolysaccharidoses (I–VII), mannosidosis, gangliosidoses, lipodoses, diabetes and associated syndromes, Pendred, Kallmann, Perrault
8. Hamartoneoplastic syndromes
Sturge-Webber, Von Hippel–Landau, Goltz, Peutz-Jegher, Maffuci
9. Gingivodental syndromes
Gingival fibromatosis and its syndromes, Rieger, tricho-dento-osseous, LADD
10. Syndromes associated with environmental and teratogenic agents*
Fetal alcohol, rubella, thalidomide, vitamin A
11. Chromosomal syndromes*
Trisomy 21, trisomy 13, trisomy 18, cri-du-chat, Wolf-Hirshhorn, Turner, FragileX
12. Associations*
CHARGE, MURCS, VATER, or VACTERL
13. Sequences*
DiGeorge, Klippel-Feil, Robin, Potter
14. Spectra*
Facio-auriculo-vertebral, oromandibular limb hypogenesis
15. Miscellaneous syndromes*
Jervell and Lange-Nielsen, Kartagener, Shprintzen, Coffin-Lowry, Kabuki make-up, Keutel, Pallister-Hall, Floating-Harbor

II. Classification of Otolaryngologic Syndromes and Conditions (Based on Eetiology)

1. Chromosomal abnormalities
Turner, Down (trisomy 21), trisomy 13, trisomy 18, cri-du-chat, 4p-, 9p-
2. Microdeletion chromosomes
Velocardiofacial (Shprintzen), Williams, Rubinstein-Taybi, Langer-Gideon
3. Single gene disorder
a. AD: achondroplasia, Marfan, neurofibromatosis (NF), Noonan, Apert, Crouzon
b. Autosomal recessive: phenylketonuria (PKU), Bardet-Biedl, Smith Lemli Opitz
c. X linked: Aaskog, ichthyosis, aqueductal stenosis
d. Mitochondrial
4. Environmental and teratogenic
Rubella, thalidomide, dilantin, PKU embryopathy
5. Multifactorial
Anencephaly, cleft lip/palate, congenital heart disease
6. Syndromes with uncertain etiology
Klippel-Feil, Cornelia-de Lange, associations

APERT SYNDROME

Acrocephalosyndactyly Type I

The major diagnostic criteria are the craniosynostosis and syndactyly of the hands and feet.

The skull is acrocephalic with a shortened anteroposterior diameter and a flat occiput. The craniosynostosis involves the coronal suture. However, the acrocephalic feature of Apert syndrome is not only due to synostosis of the coronal suture, but is a result of the primary disturbance in growth of the cranial base with precocious endochondral ossification (4). The forehead is prominent. The fontanelles are large and close at a later age. The palpebral fissures are downslanting. The corners of the mouth are downturned, and it is sometimes described as "trapezoid mouth." Dental anomalies include delayed and ectopic

*These entries do not represent other systems; their inclusion in the classification is meant to help the reader memorize the different conditions.

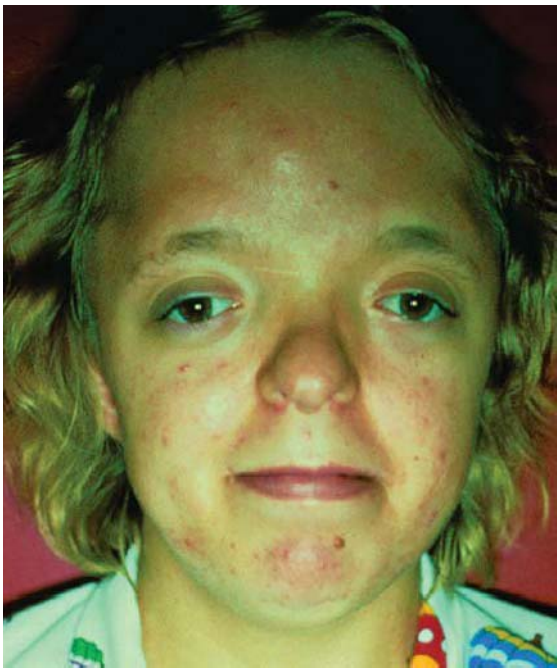

Figure 107.4 Apert syndrome: Typical facies of Apert's syndrome. Note antimongoloid slanting of the palpebral fissures, exophthalmos, hypertelorism, oxycephaly, and midfacial hypoplasia. Photo Courtesy of Meinhard Robinow, MD from Gold DH, Weingeist TA. *Color atlas of the eye in systemic disease.* Baltimore, MD: Lippincott Williams & Wilkins, 2001, with permission.

eruptions and shovel-shaped incisors. Malocclusion with mesial molar occlusion and severe crowding of the teeth are also frequently noted. A significant number of patients with Apert syndrome are mentally retarded. Malformations of the corpus callosum, the limbic structures, or both do occur. Other findings include gyral abnormalities, megalencephaly, hypoplasia of the white matter, and heterotropic gray matter. Of patients, 70% have normal intelligence (4,5).

The pituitary fossa and the basiocciput are significantly larger than normal in patients with Apert syndrome. Anomalies of the hands include syndactyly of the second, third, and fourth fingers that form a mid-digital mass (Fig. 107.4). The first and fifth fingers may join the hand mass or be separate from it. The distal phalanx of the thumb is often broad. Syndactyly is also noted in the feet and involves the second, third, and fourth toes. Fusion of the tarsal bones and an extra metatarsal have been noted. Other anomalies include abnormalities of the cervical vertebrae (single fusion 37%, multiple fusion 31%). C5 and C6 are often involved. Moderate to severe acne at adolescence occurs in 70% of patients. Synostosis of the radioulnar complex, pyloric stenosis, ventricular septal defects, and polycystic kidneys are rare occurrences.

The nasal bridge is depressed, and the midface usually is hypoplastic. The palate is narrow and is described as "byzantine-arch shaped." Cleft palate may also occur (30%). Anomalies of the ears include otitis media, conductive hearing loss, fixation of the stapedial foot plate, and wide cochlear aqueduct. Temporal bone studies revealed absence of the internal auditory canals (IACs) in one patient and enlarged subarcuate fossa in another report. Anomalies of the airway as well as tracheal stenosis, obstructive sleep apnea (OSA), and *cor pulmonale* with resultant early death were also reported (3,4). In general, OSA is related with a lower quality of life in children with syndromic craniosynostosis. Behavioral problems are more common in boys with Apert syndrome. OSA-18 scores are correlated with OSA severity (4).

The syndrome is AD inherited. An increased paternal age is a factor in sporadic cases, which accounts for the majority. The incidence of Apert syndrome is estimated to be 15.5 per 1 million, and it represents 4.5% of all cases of craniosynostosis. Mutations have been found in FGFR2 (3). The primary site of the acrocephalic feature in Apert syndrome is a dwarf cranial base with accelerated chondrocytic differentiation due to aberrant activation of the FGFR2 signaling (5).

BRANCHIOOTORENAL SYNDROME

Melnick-Fraser Syndrome

The association of auricular malformations, branchial fistulae, deafness, and renal anomalies was first described in 1975. The prevalence is estimated to be 1:40,000 in the general population.

Renal dysplasia is reported in more than two-thirds of patients and varies from tapered superior poles (duplication of the collection system) to marked agenesis of the kidney. The syndrome may include Potter sequence. Mitral valve prolapse is a new finding in BOR syndrome. It was reported in five individuals from the same family (1,7).

The preauricular pits are blind, pin head-sized depressions in the superior part of the pinna of the ear. They are seen in 75% to 85% of the patients. Other external ear malformations (40% to 60%) may include preauricular tags, lop or bat ears, and microtia (Fig. 107.5A and B). The external auditory canals (EACs) may be atretic. Anomalies of the middle ear include anomalies of the ossicles, facial nerve, and fallopian canals. Computed tomography (CT) of the temporal bones may demonstrate hypoplastic cochlea and absent or hypoplastic semicircular canals. Mondini dysplasia, widened vestibular aqueduct, and vestibular sac were also reported. The hearing loss is usually stable and may be conductive, sensorineural, or mixed. It is estimated that 2% of profoundly deaf children have BOR syndrome. The branchial fistulae (63%) are usually bilateral in the lower part of the neck, and the external openings are on the medial border of the sternomastoid muscle. Other associated manifestations include aplasia or stenosis of the lacrimal ducts (8% to 9%), high-arched or cleft palate, deep overbite, and facial nerve anomalies.

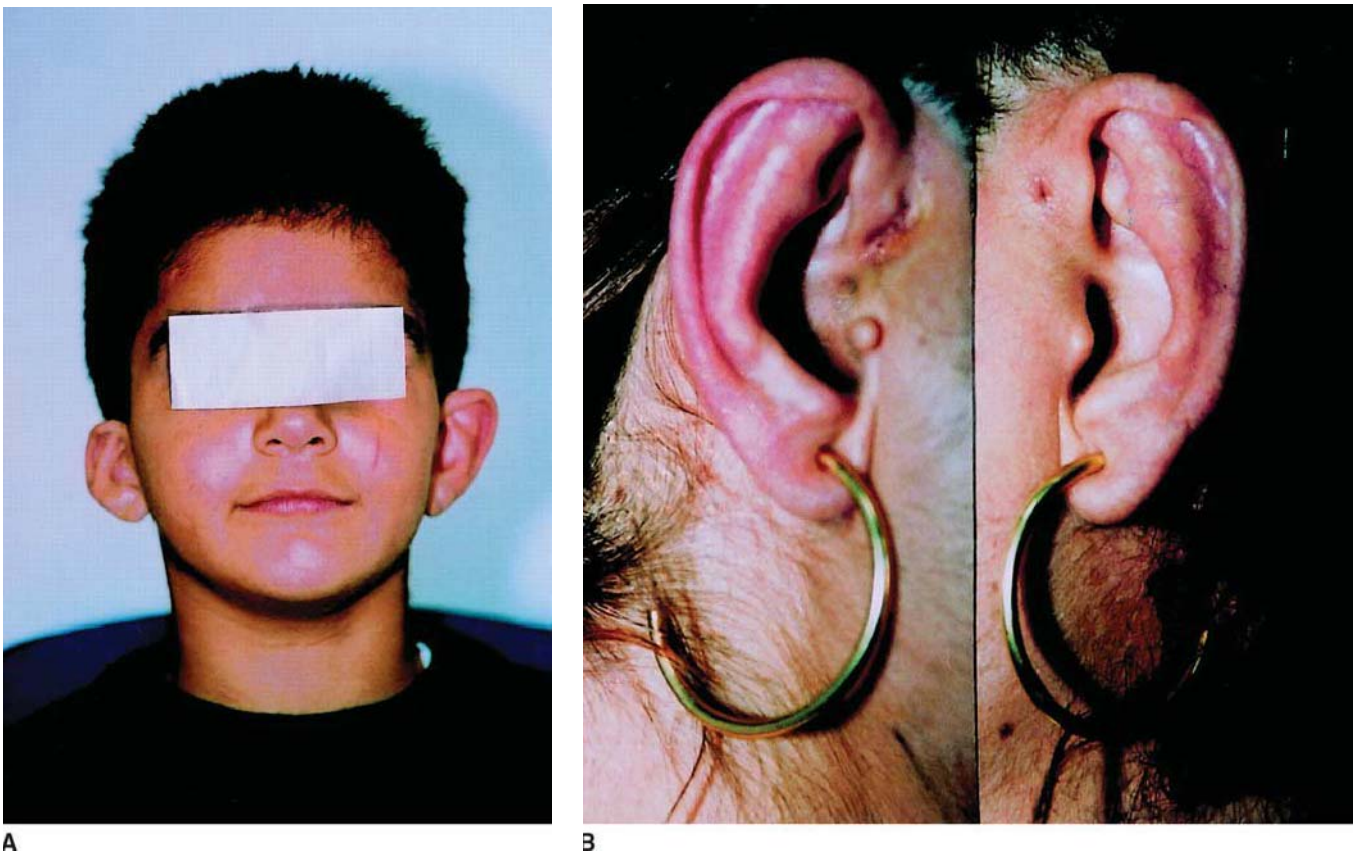

Figure 107.5 **A,B:** Branchiootorenal syndrome (BOR) syndrome. Note the ear deformity in **(A)** and the preauricular pit in **(B)**. From Pierides AM, Athanasiou Y, Demetriou K, Koptides M, Deltas CC. A family with the branchio-oto-renal syndrome: clinical and genetic correlations. *Nephrol Dial Transplant* 2002;17:1014–1018.

BOR syndrome is AD with high penetrance and variable expression. Pathogenesis is presumed to be the result of deficiency in the differentiation of the first and second branchial arches. The anomalies of the renal system are the result of abnormal interaction between the ureteric bud and the metanephric blastema. It is interesting to note that the inner ear (stria vascularis) and the renal glomeruli share a common antigen and more than one group has described histopathologic changes on temporal bone examinations (1). Mutations in EYA1 are the most common cause of branchiootic syndrome. Large chromosomal aberrations of 8q13, including complex rearrangements, occur in about 20% of these individuals. However, submicroscopic deletions and the molecular characterization of genomic rearrangements involving the EYA1 gene have been rarely reported (1,2,6,7).

CHARGE ASSOCIATION

The components of the CHARGE condition are as follows: C (*c*oloboma of the eye), H (*h*eart disease), A (*a*tresia of the choanae), R (*r*etarded development and growth), G (*g*enital anomalies), and E (*e*ar anomalies, deafness, or both).

Choanal atresia is associated with more than 65% of cases. It is bilateral in more than two-thirds of the patients. In unilateral cases, it is more common on the left side. The colobomatous malformations are seen in 80% of the cases. They range from iris coloboma with intact vision to anophthalmia and retinal colobomas. Microphthalmia and nystagmus may also occur. Cardiac anomalies may include tetralogy of Fallot, patent ductus arteriosus, ventral septic defects, atrial septic defects, coarctation of the aorta, or right-sided aortic arch. Mental deficiency is reported in the majority of cases, ranging from mild to severe. Central nervous system (CNS) malformations have also been described, such as arrhinencephaly or holoprosencephaly. Agenesis of the internal carotid artery was recently reported (1,8).

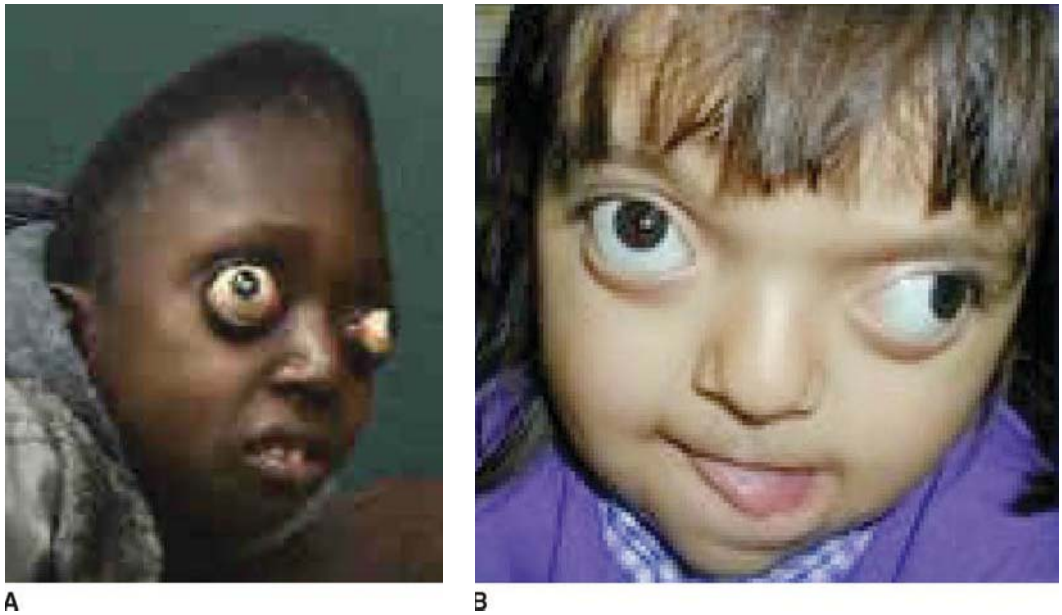
Minor kidney anomalies, cryptorchidism, microphallus, congenital hypothyroidism, imperforate anus, and pectus carinatum have also been reported.

Anomalies of the external ear include low-set ear or posteriorly angulated, asymmetric, or cup-shaped pinnae (Fig. 107.6). Anomalies of the inner ear have been coined as "charge dysplasia of the temporal bone"—which includes Mondini dysplasia of the pars inferior and complete absence of the pars superior. The hearing loss is conductive or sensorineural and often asymmetric (1).

Other anomalies include Robin or DiGeorge sequence, facial asymmetry, micrognathia, feeding difficulties,

Figure 107.6 A CHARGE association. Note the low-set posteriorly angulated pinna. Description = CHARGE syndrome: unusually shaped ears showing cochlear transplant. From Blake KD, Prasad C. CHARGE syndrome. *Orphanet J Rare Dis* 2006;1:34.

tracheoesophageal (TE) fistula, esophageal atresia, cleft lip or palate, and upper airway abnormalities.



In most cases, the syndrome is sporadic. The CHARGE association is most probably the result of an abnormality in the migration or development of the cephalic neural crest cells (1,2). AD or recessive inheritance has been suggested. Translocations involving chromosome 6 and 8 have been reported. Other chromosomal abnormalities have also been suggested. The CHD7 gene on chromosome 8q12.1 was recently shown to be a major gene involved in the etiology of CHARGE syndrome (2,8).

CROUZON SYNDROME

Craniofacial Dysostosis

Craniofacial dysostosis is characterized by cranial deformity resulting from premature craniosynostosis, hypoplastic midface, exophthalmos, hypertelorism, and mandibular prognathism. The syndrome is estimated to occur in 16.5 people per 1 million.

Craniosynostosis of the coronal, sagittal, and lambdoid sutures may occur, giving the skull a brachycephalic shape. Occasionally, scaphocephaly or clover leaf deformity may occur. Crouzon syndrome constitutes approximately 4.8% of cases with craniosynostosis in general. Proptosis occurs in most cases secondary to the shallow orbits (Fig. 107.7A and B). It may result in exposure keratitis. Optic nerve involvement is usually evident in half of the cases. Other ocular findings include megalocornea, nystagmus, keratoconus,

A B

Figure 107.7 **A,B:** Patients with Crouzon syndrome. Note the proptosis in both patients due to the shallow orbits. **A:** From http://www.mymultiplesclerosis.co.uk/misc/petero-byakatonda.html, with permission, **B:** Courtesy of Dr. Stephen R. Cohen, with permission.

ectopia lentis, or colobomas of the iris. Frequent headaches, seizures, and mental deficiency may also occur. Acanthosis nigricans has been described in association with Crouzon syndrome. The surgical treatment is usually directed toward correcting craniosynostosis. The facial abnormalities may be corrected using the Tessier procedure.

It is estimated that 30% to 55% of patients with Crouzon syndrome have hearing loss. The hearing loss is usually conductive. The EACs may be atretic. Ossicular fixation and deformities have been described as well. Anomalies of the palate include lateral palatal swellings in 50% of cases, but cleft lip or palate is not common. The maxillary teeth are often crowded, and there is usually an anterior open bite. The nose is often parrotlike. Calcification of the stylohyoid ligament occurs most of the time. Anomalies of the cervical vertebrae involve mostly C2 and C3.

Surgical intervention involves fronto-orbital and midfacial advancement, usually done in stages in childhood. The occlusion is corrected adequately with orthodontics and final maxillary advancement after skeletal growth is completed (1).

The syndrome is inherited as an AD trait with complete penetrance. The expressivity is variable. Increased paternal age is a factor in the sporadic cases. Mutations have been described in the genes of FGFR 2. Crouzon syndrome with acanthosis nigricans results from a mutation in FGFR 3 (1,2,4,).

DOWN SYNDROME

Trisomy 21 or Down syndrome is the most common of the chromosomal abnormality syndromes. The diagnosis of Down syndrome can be made in the early newborn period. Four out of 10 signs are needed to make a clinical diagnosis (Table 107.1). However, a final diagnosis may be made only after having the results of the chromosomal pattern. Adaptive behavior in Down syndrome is described to increase until middle childhood and to begin to decline in adolescence, whereas significant deterioration in middle adulthood has been attributed to early onset of dementia. Nevertheless, opinions diverge about when the slowing down of adaptive and cognitive abilities starts. In a recent prospective cross-sectional study, Dressler et al. concluded that individuals with Down syndrome continue to increase competence in adaptive behavior until age 30, even when cognitive abilities reach a plateau. There was no major decline in middle adulthood. This may be due to exposure to daily life, but needs to be supported by further studies.

TABLE 107.1 TEN CARDINAL FEATURES OF DOWN SYNDROME IN THE NEWBORN

Features	Percentage
Flat facial profile	90
Poor moro reflex	85
Hypotonia	80
Hyperflexibility of joints	80
Excess skin on back of neck	80
Slanted palpebral fissures	80
Dysplastic pelvis	70
Anomalous auricles	60
Dysplasia of midphalanx of 5th finger	60
Simian crease	45

The eyes have speckled irises (Brushfield spots), and fine opacities are seen in the lens on slit lamp examination. Mental deficiency is a hallmark of the syndrome. The intelligence quotient (IQ) varies between 30 and 50. Various brain lesions have been described including abnormalities of the cerebellar peduncles and fibrous gliosis of the white matter. The frequency of epilepsy is estimated to be 5%. Older patients develop changes characteristic of Alzheimer disease. Cardiac anomalies are seen in approximately 40% of patients; atrioventricular communis or ventricular septal defects, Fallot tetralogy and patent ductus arteriosus occur in decreasing order of frequency. Atlantoaxial instability is seen in 10% to 20%. The hands have short metacarpals and phalanges with clinodactyly and hypoplastic midphalanx of the fifth finger. Single palmar creases and ulnar loop dermal ridge patterns are seen in a high percentage of cases. There is a wide gap between the first and second toes. Male patients have a small penis and low testosterone production and are almost all infertile. The hair is often sparse; cutis marmorata and dry hyperkeratotic skin are not uncommon (1).

Other uncommon anomalies include TE fistula, incomplete fusion of the vertebrae, cryptorchidism, syndactyly, and keratoconus. The main cause of death is the cardiovascular malformation and is highest in the first 2 years of life. Leukemia occurs in 1% of patients. Lymphomas, testicular carcinoma, and CNS tumors have also been reported. Flat facial features, small or absent paranasal sinuses, hypertelorism, small nasal bridge, and oblique palpebral (upward-slanting) fissures occur in more than 80% of patients. The tongue is relatively large and protrudes from the mouth. It may be furrowed or fissured. Occasionally true macroglossia exists. The ears are small with overfolding of the superior part of the helix. The EACs are stenotic, especially at the isthmus (bony-cartilaginous junction). Conductive hearing loss occurs in 60% of patients, with a high incidence of serous otitis. Sensorineural hearing loss (SNHL) occurs in 10% of patients. The cochlea is sometimes shorter than usual. Ossicular chain anomalies, especially the stapes, may be seen. The lips are broad and dry, and rhagade furrows around the mouth are seen (Fig. 107.8). The tonsils are often hypertrophied and not recessed in the fossae. The palate is narrow. Cleft lip or palate is occasionally seen. Gingivitis, periodontal disease, and dental caries exist. Microdontia, hypoplasia of the enamel, posterior cross-bite, and widely spaced teeth are frequent occurrences. Articulation defects and dysrhythmic or explosive speech are associated with a low-pitched hoarse voice.

Of all cases, 95% are the result of trisomy 21 with 47 chromosomes. Mosaicism is observed in 2.4% of patients.

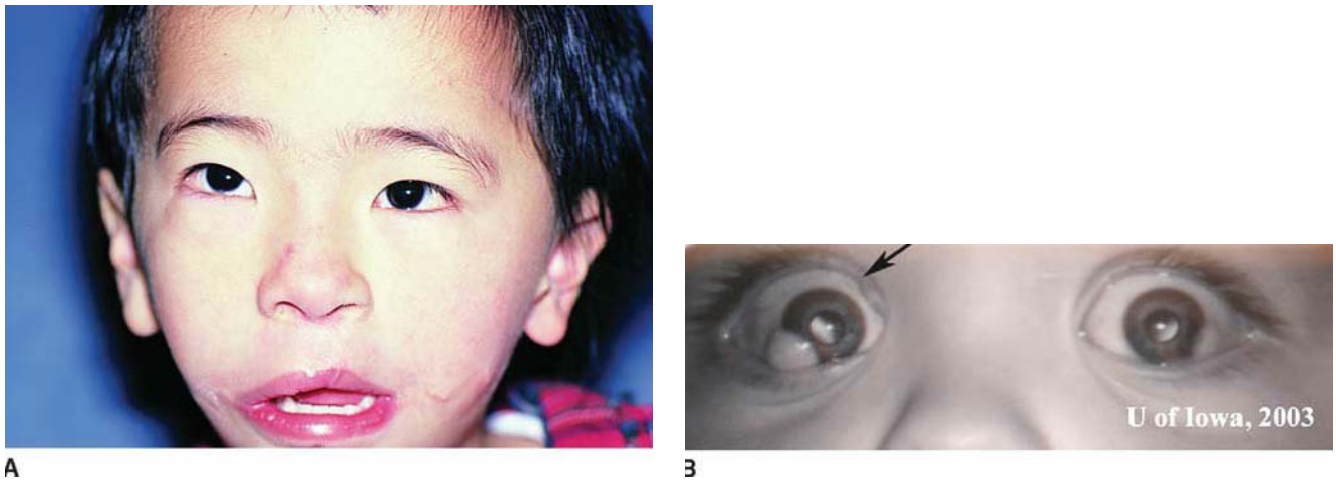


Figure 107.8 Down Syndrome. Reprinted from Pillitteri A. *Maternal and child health nursing*, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2003, with permission.

Translocations account for 3% to 5% of cases involving chromosome 14, 21, or 22 (i.e., 14/21, 21/21, or 22/21). The incidence of the syndrome increases with advanced maternal age, being 1:1,500 for mothers aged 15 to 29 and 1:50 for those older than age 40. The general incidence is 1:600 of all live births (1,2,9).

GOLDENHAR SYNDROME

Oculoauriculovertebral Dysplasia Spectrum or Facioauriculovertebral Sequence

Gorlin proposed the term *oculo-auriculo-vertebral dysplasia* for the spectrum of anomalies ranging from hemifacial microsomia (HFM) that denotes unilateral microtia, mandibular hypoplasia, and microstomia to Goldenhar syndrome, which also includes epibulbar dermoids (Fig.107.9B) and vertebral anomalies. Blepharoptosis, microphthalmia, epibulbar tumors, and retinal abnormalities have been documented. The visual acuity is usually reduced. Mental retardation varies in the reported series between 5% and 15%. Children with anophthalmia or microphthalmia and cleft lip or palate seem at increased risk for cerebral malformation and mental retardation. Various cardiac anomalies are described ranging from ventricular septal defect, patent ductus arteriosus, and Fallot tetralogy to coarctation of the aorta. Renal ectopia and hydronephrosis are less common. Talipes equinovarus deformities and other limb anomalies are rare occurrences. The mandibular ramus and condyles are hypoplastic. The maxilla, malar, and temporal bone are smaller on one side (Fig. 107.9A). The mastoid is also poorly pneumatized. Approximately one-third of the cases show bilateral involvement. The right side is involved in 60% of the cases. Macrostomia or pseudomacrostomia (lateral cleftlike extension of the corner of the mouth) is a usual occurrence. The parotid gland is also affected (agenesis or displaced salivary tissue). Cleft palate or lip occurs approximately 10% of the time. Delayed dental development, as well as lingual and palatal malformations, occurs

A B

Figure 107.9 **A:** Patient with Goldenhar syndrome: Note the unilateral microtia, mandibular hypoplasia, and microstomia B subconjunctival dermoids of the right eye in patient with Goldenhar syndrome. **A:** From Tasman W, Jaeger E. *The Wills eye hospital atlas of clinical ophthalmology*, 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2001. **B:** From Graff JM, Bhola R, Olson RJ. Goldenhar Syndrome (Oculo-Auriculo-Vertebral Spectrum): 6-day-old male with limbal dermoids on http://webeye.ophth.uiowa.edu, with permission.

on the hypoplastic side. Microtia or occasional anotia and preauricular tags occur between the tragus and the corner of the mouth. The middle ear demonstrates ossicular anomalies and abnormal course of the facial nerve. The hearing loss is more commonly conductive than sensorineural. Cervical vertebral anomalies occur in 30% of cases. Hemivertebrae and fused vertebrae have been described. Tracheal and pulmonary anomalies and TE fistula are less common (1,10,11). Esophageal atresia has been reported to occur in about 5% of Goldenhar syndrome patients. Anesthetic problems and surgical complications may be associated with gastroesophageal reflux.

Several classifications for HFM have been proposed. The most inclusive and flexible is OMENS. The acronym represents each one of the five major manifestations of HFM: O for orbital distortion, M for mandibular hypoplasia, E for ear anomaly, N for nerve involvement, and S for soft tissue deficiency. The term *OMENS-plus* is used to include the expanded spectrum: cardiac, skeletal, pulmonary, renal, gastrointestinal, and limb anomalies. Of patients with HFM classified using OMENS and analyzed statistically, 154 showed a positive association between the severity of the mandibular hypoplasia and the severity of orbital, auricular, neural, and soft tissue involvement. This study documented that HFM was associated with macrostomia (62%), facial nerve involvement (45%), ear tags (40%), palatal deviation to the normal side (39%), epibulbar dermoids (20%), horizontal discrepancy of the orbits (15%), and deformational frontal plagiocephaly (5%). The management of HFM exemplifies the need for an interdisciplinary approach to craniofacial anomalies. In the past, there has been a tendency for each specialist to concentrate on his or her own particular area of interest or expertise. The infant or child with HFM presents not only with congenital anomalies but also with the result of abnormal growth and the potential interference of prior treatment. A systematic approach focuses on the hypoplastic mandible as the key to the management of the deformity. In infancy, treatment includes excision of preauricular tags, closure of macrostomia, and transposition of the microtic ear lobule, if it is located low and anteriorly on the cheek. The mandibular deformity is graded according to the size of the mandible. Type I is a miniature mandible with identifiable anatomy; type II is a functioning temporomandibular joint (TMJ) but with an abnormal shape and glenoid fossa; type II is subcategorized as either type IIA, if the glenoid fossa is in an acceptable functional position (in reference to the opposite TMJ), or type IIB, if the TMJ is abnormally placed and cannot be incorporated in the surgical construction. Type III deformity indicates an absent ramus and nonexistent glenoid fossa.

The concept for treatment of the child with HFM is elongation of the affected ramus (types I, II) or construction of a ramus and condyle if it is missing (type III). Elongation or construction of the ramus creates an open bite on the affected side. This space is slowly closed over a period of 2 years with gradual reduction of an orthodontic splint. This appliance regulates eruption of maxillary teeth and thereby stimulates maxillary (midfacial) growth. The goal is to achieve a horizontal occlusal plane (10,11).

Type I, a mini-mandible skeletal deformity, often can be managed with a "functional" orthodontic appliance called an "activator." This device can be placed by age 3 years. If the appliance fails to prevent obliquity of the occlusal plane, then elongation of the ramus or mandibular distraction is indicated between ages 6 and 12 years during mixed dentition. If a type I deformity presents late in adulthood, then bilateral mandibular osteotomies are required to prevent abnormal forces from acting on the normal TMJ. A Le Fort I maxillary osteotomy can also be necessary. Type II mandible can also be treated for a time with a "functional" appliance; however, all children with type II mandible require mandibular elongation. Children with type IIA mandible have a well-placed but short ramus. They are candidates for a vertical osteotomy and elongation or a simple oblique or transverse corticotomy and gradual mandibular distraction. In type IIB or type III mandible, construction of the ascending ramus is needed, usually when the child has a full complement of deciduous teeth. TMJ reconstruction has been done by some as early as age 2 years and by others between age 6 and 12 years. Patients with type III mandible rarely present in adulthood. These patients require full construction of the mandible, TMJ, zygomatic arch, and in some cases a leveling orbital osteotomy. Le Fort I or maxillary osteotomy is required to give a level occlusal plane and symmetry. The condyle is constructed with costal cartilage, and bone graft is used to construct the glenoid fossa. Sliding genioplasty is often necessary in combination, with or without a mandibular procedure as the final surgical step for the young adult with HFM.

Ear construction must be conceptualized prior to mandibular correction to avoid improper placement of incisions and scarring. In high-grade mandibular deformity (i.e., type IIB or type III), it is usually best to defer ear construction until skeletal symmetry is achieved, usually after 10 years of age. In low-grade mandibular hypoplasia, the ear construction can be done any time after age 6 years, when the costochondral elements are large enough to build an autogenous auricular framework.

Soft tissues can be hypoplastic in HFM. In rare cases, after restoration of the skeletal framework, soft tissue must be added. Onlay bone grafts to the ramus usually give symmetric lateral facial contour. Free tissue transfer by microsurgical techniques is another option. In minor cases, a dermal graft can be sufficient.

"Mandibular distraction" is a new method for ramus elongation for type I, type IIA, and some type IIB mandibles. This technique was originally described for long bones by Ilizarov in Russia. It involves an osteotomy (corticotomy) and placing metallic pins through the hypoplastic ramus on each side of the osteotomy. The distraction device is attached and secured to the pins, and then the device is turned 1 mm/day. The mean amount of

lengthening or distraction is 24.5 mm at a rate of 1 mm/day. It can be done as early as 2 years of age. Distraction osteogenesis gives more mandibular bone than with elongation by sliding vertical osteotomy or rib graft construction. Careful follow-up documentation of the ramus height and occlusal plane is necessary. Nevertheless, the concept and possibilities for skeletal distraction are very promising for the ramus and for correction of other craniofacial skeletal abnormalities.

The syndrome occurs sporadically in the majority of cases. Of reported cases, 1% to 2% occur in families, suggesting AD transmission. Animal models showed that vascular disruption and hematoma formation affect the developing structures of the jaw and ear regions *in utero*. Other hypotheses suggest that disturbance of the population of the neural crest cells occurs during the 30th to 45th days of gestation. The frequency of the condition ranges between 1:3,500 and 1:25,000 births (1,2,11,12).

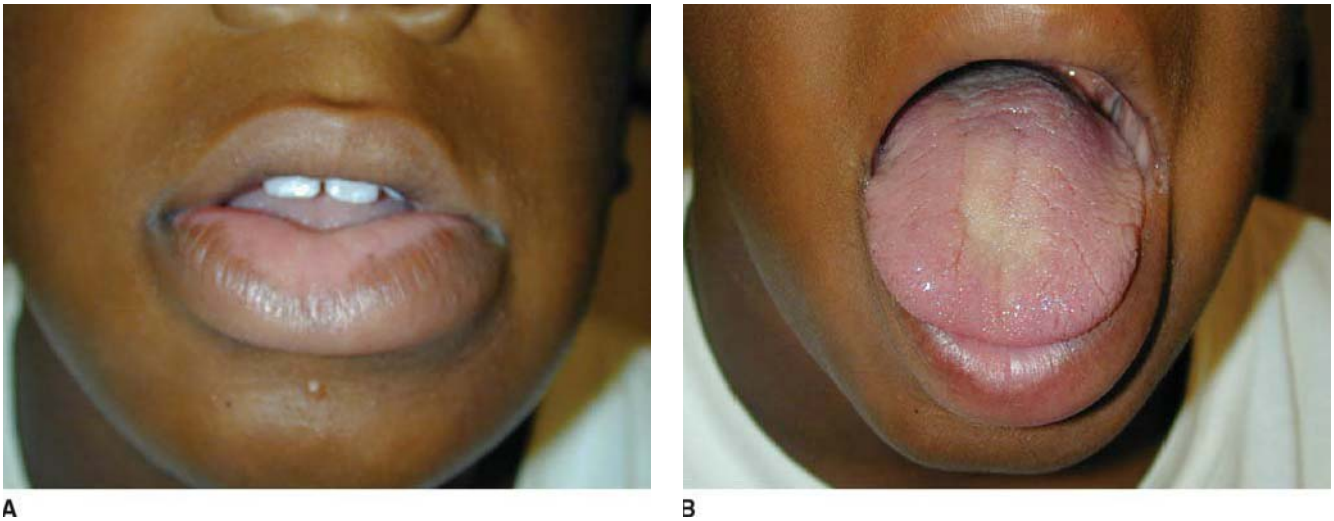
KARTAGENER SYNDROME

Dextrocardia, Bronchiectasis, and Sinusitis

Pansinusitis in childhood, absence of the frontal sinuses, and thick nasal rhinorrhea are characteristic presenting symptoms of Kartagener syndrome. The mastoid air cells are poorly developed. Otitis media as a result of eustachian tube dysfunction results in deafness, usually of the conductive type. Anosmia and nasal polyps are frequent complications. Recurrent pneumonia and chronic cough are common. It is estimated that one-tenth of the cases of bronchiectasis are the result of Kartagener syndrome.

Situs inversus with gross defects in cardiac septation may occur. One-sixth of situs inversus cases have the syndrome. Myringotomy and insertion of bilateral tympanostomy tubes are required for treating the serous middle ear effusion. However, a recent retrospective study demonstrated that despite continuous antibiotic therapy, the middle ear condition in primary ciliary dyskinesia remained severe throughout childhood, with improvement only after age 18. Tympanostomy tube placement did not improve the middle ear condition (1,13).

Early treatment of respiratory infection may help in preventing bronchiectasis. Removal of affected lobes of the lung may be needed later to treat the bronchiectasis. *In vitro* fertilization may be used in the management of sterility. Associated anomalies include polysplenia or asplenia syndrome, rheumatoid arthritis, thyrotoxicosis, biliary atresia, abnormal subclavian artery, and glomerulonephritis (13).



The mode of inheritance is autosomal recessive. AD or X-linked inheritance has also been suggested. The primary defect is abnormality of the cilia of the respiratory tract. This leads to blockage of the paranasal sinuses, Eustachian tubes, and the lungs. Immobility of the sperm produces sterility in the males; affected females may have decreased fertility. The lack of dynein arms is the most common structural abnormality in the respiratory and fallopian cilia and the sperm tails (1,2,13).

MELKERSSON-ROSENTHAL SYNDROME

Cheilitis Granulomatosa

Melkersson-Rosenthal syndrome is characterized by recurrent or persistent lip swelling, facial swelling, facial palsy and furrowed tongue, auditory and visual disturbances, swelling in the hands and chest, blepharospasm, epiphora, and megacolon. Other eponyms of the syndrome include (Fig. 107.10A and B):

Miescher cheilitis, Melkersson-Rosenthal-Schuermann syndrome, Melkersson syndrome, Rossolimo-Melkersson-Rosenthal syndrome, and Rosenthal syndrome II (14,15). Surgical excision and reconstruction are recommended for the swollen orofacial tissues. Total facial nerve decompression for recurrent facial palsy is also advocated.

A B

Figure 107.10 **A,B:** Furrowed tongue and lip swelling in Melkerson-Rosenthal syndrome. From http://dermatlas.med.jhmi.edu/ Copyright Dr. Bruce Cohen with permission.

The swelling of the lips is usually of sudden onset, unilateral or bilateral. The upper lip is affected in most cases and may remain swollen permanently. This occurs in 75% of patients. The facial palsy occurs after the lip swelling and sometimes precedes it. The facial swelling usually involves the eyelid, chin, and forehead in 50% of cases. The oral mucosa and the gingiva may show swelling. Histologically, the swollen tissues exhibit chronic granulomatous changes similar to sarcoidosis or tuberculosis (1). Orofacial granulomatosis is a generic term applied to manifestations of several diseases including sarcoidosis, Crohn's disease, Melkersson-Rosenthal syndrome, tuberculosis, and foreign body reaction. What bonds these conditions together is the presence of noncaseating granulomas (1,15).

The lingual fissures occur in 40% of the cases. Defects of taste along the anterior two-thirds of the tongue, lip fissuring, and exposure keratitis are seen in long-standing cases.

Most cases of Melkersson-Rosenthal syndrome are sporadic. Familial occurrences suggest an AD transmission. The syndrome is remarkably variable in its expression. The disease begins in childhood or early adulthood. It is considered a local immune response and vasomotor disturbance affecting the vasa vasorum of the vessels supplying the facial nerve and neighboring structures (2,15).

NEUROFIBROMATOSIS 1

Von Recklinghausen Disease or NF1

The criteria for diagnosis of NF1 include two or more of the following: more than five café-au-lait spots with or without axillary or inguinal freckling; multiple cutaneous neurofibromas; or at least one plexiform neurofibroma, optic glioma, Lisch iris nodule, a distinct bony lesion such as tibial bowing or pseudoarthrosis, sphenoid wing dysplasia, and affected first-degree relative.

The café-au-lait spots and axillary freckling may be present at birth and become more evident with age.

The presence of multiple café-au-lait, large segmental café-au-lait, associated facial dysmorphism, other cutaneous anomalies, or unusual findings on physical examination should suggest the possibility of an associated syndrome. While NF type 1 is the most common syndrome seen in children with multiple café-au-lait, other syndromes associated with one or more café-au-lait include McCune-Albright syndrome, Legius syndrome, Noonan syndrome and other neuro-cardio-facio-cutaneous syndromes, ring chromosome syndromes, and constitutional mismatch repair deficiency syndrome (16). Cutaneous neurofibromas may be sessile or pedunculated. They develop around the second decade and increase with age as well. Plexiform neurofibroma occurs in one-third of the patients (Fig. 107.11). Malignant degeneration is estimated to be 5% to 15%.

Mental retardation, learning disabilities, and speech defects are not uncommon. Macrocephaly, hydrocephalus, aqueductal stenosis, and seizures may occur (2,16).

Lisch iris nodules are present in 90% of patients. They cause no visual impairment. Other ocular findings include optic glioma (15%), optic nerve meningioma, and congenital glaucoma (1%).

Multiple organ involvement may cause serious complications. Paraspinal, retroperitoneal, mediastinal, renal, laryngeal, and cardiac tumors are reported. Acoustic neuromas do not occur in NF1. Scoliosis, kyphosis, and cervical spine anomalies may develop.

Precocious puberty, hypopituitarism, gigantism, hypogonadism, intracranial calcifications, and diabetes insipidus have been described.

Velopharyngeal insufficiency, macroglossia, jaw lesions, hypoplasia of the facial bones, enamel, and dentin defects may be seen.

NF1 syndrome is AD. NF1 gene location is in the 17q11.2 region. Fresh mutations represent about 50% of cases. The prevalence is 1:3,000. NF1 is caused by deletions, insertions, translocations, and point mutations in the NF1 gene, which spans 350 kb (1,2,16).

NEUROFIBROMATOSIS 2

Café-au-lait spots and cutaneous neurofibromas are not consistent findings of NF2. Axillary freckling is uncommon. Other neurogenic tumors are common. They include schwannomas, intracranial or spinal meningiomas, or astrocytomas. Increased symptoms may be noted during late pregnancy. Posterior capsular cataracts are common (80%). Lisch nodules are absent in NF2. The symptoms usually develop unilaterally, and involvement of the other side occurs within 2 years.

Diagnostic criteria include the following:

1. Bilateral acoustic neuroma seen with appropriate imaging technique (CT or magnetic resonance imaging [MRI]), or
2. A first-degree relative with NF2 and either unilateral 8th nerve mass, or two of the following: neurofibroma, meningioma, glioma, schwannoma, or juvenile posterior subcapsular lenticular opacity. The incidence is estimated to be 1:50,000.

Symptoms are usually the result of pressure on the vestibulocochlear (VIII nerve) and facial nerve complex. Hearing loss is often the first symptom, which occurs in the teens or early 20s with an average age of 20. Tinnitus, imbalance, and vertigo accompany the deafness. Small acoustic neuromas of less than 8 mm were detected in asymptomatic children (aged 7 and 11) by the use of gadolinium-enhanced MRI. One patient had normal audiometry and brainstem-evoked responses.

Other symptoms of facial pain, numbness or weakness and paralysis, headache, diplopia, nausea, and vomiting may develop. Cervical kyphoscoliosis may be related to a paraspinal neurofibroma.

NF2 is AD, with 95% penetrance and linkage to 22q11-q13. The NF2 gene has been isolated. It encodes a protein named merlin. Mutational analysis of patients has been done (1,17).

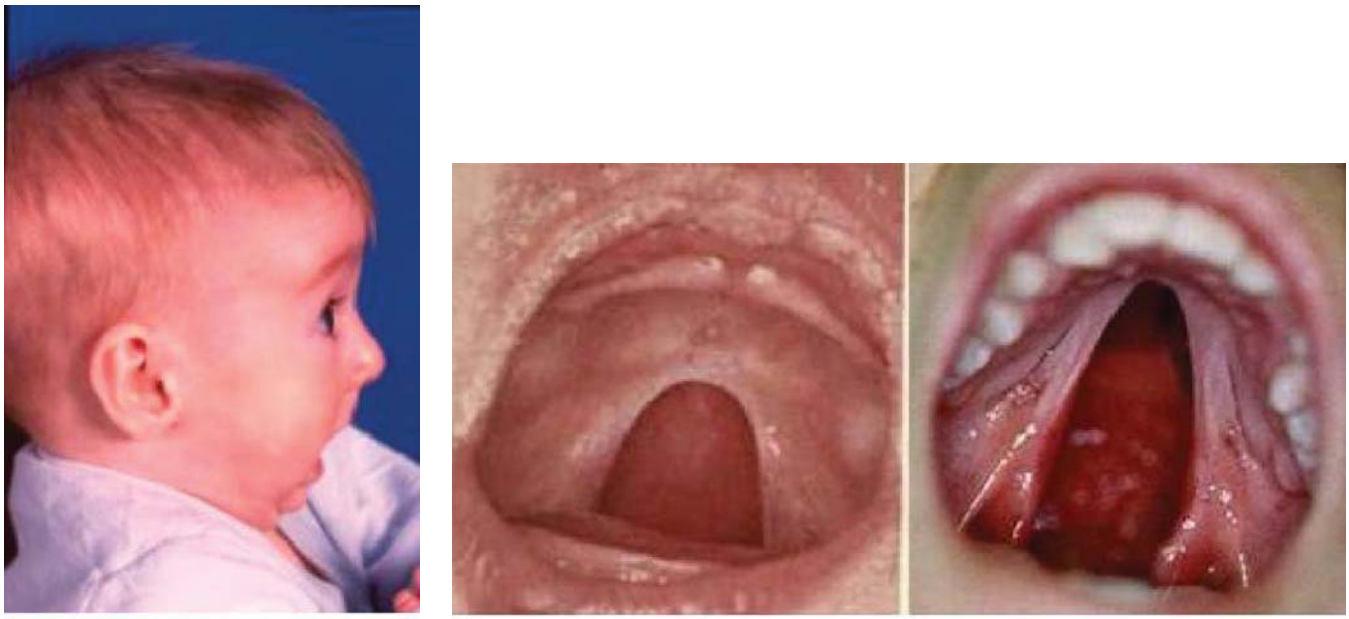


Figure 107.11 **A:** Patient with PRS with micrognathia and recessed chin. **B:** Inverted U and inverted V types of cleft palate in PRS.

ROBIN SEQUENCE

The major diagnostic criteria of Robin sequence are micrognathia, glossoptosis, and inverted U-shaped cleft palate. Congenital heart defects are associated with Robin sequence in 14% of cases. Limb anomalies, ocular malformations, rib and sternal abnormalities are described. The infant is kept in the prone position, and respiration is monitored. Repair of the cleft palate is done at a later age.

In a recent study comparing the jaw size, jaw relationship, and facial proportions of children with Pierre Robin Sequence (PRS) to children with nonsyndromic or isolated cleft palate (iCP). The authors found that during early childhood (1 to 4 years) mandibular and maxillary lengths were similar in both PRS and iCP groups. In older children (10 to 13 years), mandibular length was significantly shorter in the PRS group compared to the iCP group. Maxillary length in PRS and iCP groups was similar, but significantly shorter in comparison to age-matched norms with a difference 14.5 mm ($P = 0.037$) for PRS and 12.4 mm ($P = 0.045$) for iCP (1,18). Radiologically, the mandibular ramus and body are smaller than normal and the mandibular angle is obtuse (19).

Respiratory difficulty with periodic cyanotic attacks are associated with sternal retraction and are more apparent when the baby is in the supine position (2,18,20).

A few patients may require tracheotomy for airway management in the first 3 years of life (Fig. 107.11A and B). Distraction osteogenesis has been described as an alternative surgical treatment.

Robin sequence is very heterogeneous with birth prevalence of 1:8,500. The initial defect is thought to be hypoplasia of the mandible, before 8 weeks of gestation. This would result in the posterior location of the tongue, which prevents the closure of the posterior palatal shelves. The cleft is different from the usual inverted V-shaped cleft that is not the result of mandibular involvement. Oligohydramnios is thought to play a role in the pathogenesis. The reduced amniotic fluid will result in compression of the chin and impaction of the tongue between the palatal shelves. Other hypotheses include neurogenic hypotonia and connective tissue disorder (2,18).

Differential Diagnosis

Robin sequence may occur as an isolated anomaly, but it may also be a feature of a malformation syndrome. Examples are diastrophic dysplasia, Nager acrofacial dysostosis, otopalatodigital syndrome II, popliteal pterygium, Stickler, Shprintzen, del 6q, Möbius, and other syndromes, as well as CHARGE association (1,2).

SHPRINTZEN SYNDROME

Shprintzen described the syndrome in 1978. Previous reports are found in the literature describing patients with similar features. The ocular findings include retinal vascular tortuosity, posterior embryotoxon, narrow palpebral fissures, suborbital discoloration, small optic nerves, iris nodules, and cataracts. The cardiothoracic anomalies include pulmonary atresia, ventricular septal defects, and hypoplastic pulmonary arteries. Severe abnormalities of the arborization of the pulmonary arterial tree were reported.

Figure 107.12 **A,B:** Patient with velocardiofacial syndrome. Note that the nose is tubular, mandible is retrognathic, and the philtrum is elongated.

Fallot tetralogy, aberrant subclavian arteries, and right-sided aortic arch are also described. The fingers appear tapered and slender in most cases. Most children experience learning disability and difficulty with abstraction and reading comprehension. Verbal IQ score ranged between 69 and 87 in one study (21). Other less common traits include herniae (inguinal or umbilical), hypocalcemia, and absent thymus. The nose is prominent and tubular, and the alae nasi and nasal cavities are hypoplastic. The mandible is retrognathic, and the vertical diameter of the maxilla is increased (Fig. 107.12A and B). The upper lip and the philtrum are elongated. More than 80% of cases have adenoid hypoplasia, which contributes to the nasal speech. Velopharyngeal insufficiency and hypernasal speech are the main presenting symptoms. Approximately 15% of the patients have Robin sequence, and 35% have cleft palate. OSA is common. Some authors classify the facial features into humorous or nervous depending on the pursed lips versus the upslanting palpebral fissures. Hearing loss of the conductive type is more frequent than the sensorineural variety. The pinnae are usually small (1,12,22). Roizen et al. studied the motor function in children with 22q11.2 deletion syndrome (22q11.2) and a Full Scale IQ comparable control group. They concluded that school-aged children with 22q11.2 have specific motor deficits in axial stability and graphomotor skills (23).

Velocardiofacial syndrome is AD. Velocardiofacial and DiGeorge syndromes may represent part of a spectrum seen with monosomy for 22q11 (1,2).

TREACHER COLLINS SYNDROME

Franceschetti-Zwahlen-Klein Syndrome or Mandibulofacial Dysostosis

Diagnostic criteria of Treacher Collins syndrome include microtia and malformed ears, hypoplastic midface, downslanting of the palpebral fissures, coloboma of the outer third of the lower eye lids, and micrognathia. Most patients have normal intelligence. Developmental retardation is reported in only 5% of cases. Delays are probably secondary to undetected hearing loss. The most common ocular findings are lower lid colobomas (77%) with absence of cilia medial to the coloboma (Fig. 107.13). Microphthalmia and coloboma of the iris may occasionally be seen. Other uncommon anomalies include congenital heart defects and cryptorchidism. The facies are characteristic. The supraorbital ridges are flat. The nose appears large because of the depressed malar bones. The lower nasal cartilages are underdeveloped. The bridge of the nose is often high. The auricles are malformed, and microtia is reported in 60% to 77% of the cases. The EACs are stenosed or absent. In the middle ear,

Figure 107.13 Treacher Collins syndrome.

different anomalies are described such as monopodal stapes, ankylosed foot plate, bony bridge to the fallopian canal, and malformed incus. The tympanum may be filled with connective tissue, and the epitympanum and mastoid show different degrees of hypoplasia or agenesis. The cochlea and vestibule may show abnormalities. The hearing loss is usually conductive. A sensorineural component has also been described. One-third of the patients have cleft palate or velopharyngeal insufficiency. Macrostomia and hypoplasia of the parotid glands are also seen. The coronoid process of the mandible is flat, and the condyles may be malformed. Blind fistula between the auricle and angle of the mouth, choanal atresia, and pharyngeal hypoplasia are occasional abnormalities. Five categories are described by Franceschetti, depending on the number of features present. In Tessier classification, the complete form of the syndrome manifests craniofacial clefts 6, 7, and 8. These patients have a complex craniofacial malformation involving the middle and lower parts of the face and affecting both bony structures and soft tissues. The deformity is always bilateral and nearly always symmetric. They have downward-sloping palpebral fissures, depressed cheekbones, deformed pinnas, receding chin, and wide oral commissures (macrostomia). This syndrome can be mistaken for bilateral HFM. The degree of symmetry and normal facial nerve function are important distinguishing characteristics of Treacher Collins syndrome. Plain radiographs reveal the malar hypoplasia, "tear drop"-shaped orbits, and partial or complete absence of the zygomatic arches. In severe cases, there is absence of the lateral wall and the floor of the orbits (i.e., a clefting of the inferolateral orbit extending into the sphenomaxillary [inferior orbital] fissure). Mandibular retrognathism is present, with shortening of the body and the ramus of the mandible. The chin is retruded severely, and the nasomaxillary area is relatively prominent. These children usually have normal intelligence (1,2,24,25).

The upper airway narrowing and the hearing impairment are major issues in infancy. These infants are prone to OSA and sudden infant death syndrome. The size of the nasopharynx in Treacher Collins syndrome is about 50% smaller than normal. The surgical plan for Treacher Collins syndrome must be tailored to the patient's specific deformities, taking into consideration facial growth and psychosocial impact. The surgical correction can be separated into procedures for the upper face and those for the jaws or lower face (1,25).

Treacher Collins syndrome has an AD inheritance with variable expressivity and high penetrance. A recessive form has also been described. Experimental embryologic studies using vitamin A and isotretinoin produced similar changes in rats, hamsters, and mice. Hypersensitivity of the mother to vitamin A has also been suggested. The proposed gene location is 5q11 (1). Trainor (26) explains the role of neural crest cells in the etiology and pathogenesis of Treacher Collins syndrome.

USHER SYNDROME

The incidence of Usher syndrome is estimated to be 3 to 5 per 100,000 in the general population and 1% to 10% among children who are profoundly deaf. Clinical manifestations are deafness and retinitis pigmentosa. Ocular findings include cataracts in 50% of patients by age 40 and occasionally glaucoma. Mental deficiency, psychosis, ataxia, and cataracts are sometimes associated with retinitis pigmentosa and deafness and termed "Hallgren syndrome." Abnormalities of nasal cilia and sperm axonemes have been described. The prognosis is a normal life span. Social and vocational preparation for adults who are deaf and blind is required (1,27,28).

Clinical Types

Usher, type I: Profound congenital deafness and loss of vestibular functions, onset of retinitis pigmentosa before puberty (around the age of 10 years). This constitutes 90% of the patients.

Usher, type II: Hearing loss is moderate to severe from birth, and the vestibular functions are normal. Onset of retinitis pigmentosa is in the late teens.

Usher, type III: Progressive hearing loss; retinitis pigmentosa begins at puberty.

Usher, type IV: Clinically similar to type II but with X-linked recessive inheritance.

Types III and IV constitute less than 1% of patients. The findings in the retina are described as pallor of the optic disc, "bony spicule" concretions of pigment, and arteriolar narrowing.

The changes in the temporal bone involve the cochlea. Marked atrophy of the organ of Corti in the basal turn is associated with spiral ganglion degeneration. These cochlear changes are similar to Scheibe inner ear dysplasia.

Usher syndrome has an autosomal recessive inheritance in most cases and an X-linked recessive inheritance in rare instances (1,2,27). To characterize visual function in defined genotypes including siblings with

Usher syndrome, Malm et al. (28) concluded that the evaluation of visual function comprising both the severity of the rod cone degeneration and the function in the macular region confirm phenotypical heterogeneity within siblings and between different genotypes of Usher syndrome.

WAARDENBURG SYNDROME

Along with congenital sensorineural deafness there are multiple congenital anomalies. The widely spaced medial canthi (dystopia canthorum) is characteristic of type I. Lack of penetrance of this sign occurs in no more than 1% of cases. Confluent eyebrows with hypertrichosis of their medial portions (synophrys) is present in 85% of type I and 25% of type II. White forelock (poliosis) occurs in 20% to 40% of the time in type I or II. (Fig. 107.14A and B).

Localized hypopigmentation can also be found in piebaldism and Tietz syndrome, whereas diffuse forms are typical for oculocutaneous albinism, Hermansky-Pudlak syndrome, Chediak-Higashi syndrome, and Griscelli syndrome. Heterochromia iridis occurs in 30% of patients of both types (29).

Other findings include craniosynostosis, blepharophimosis, glaucoma, mild prognostic mandible, Hirschsprung megacolon, premature graying of hair, anophthalmia with limb malformations, ventral septal defects, meningocele, spina bifida, hypoplasia of the shoulder girdle, and axillary webbing (1,29,30).

Clinical Types

Type I: Dystopia canthorum present; this condition is 20 times more common than type II.

Type II: Dystopia canthorum not present; hearing loss (50%) as well as pigmentary disorders is more common in this type.

Type III: Klein-Waardenburg syndrome or pseudo-Waardenburg, no dystopia canthorum but with one-sided ptosis of the upper eyelid and upper limb anomalies.

A Waardenburg-Hirschsprung disease association clinical type has also been described.

Symptoms include deafness, broad nasal bridge, hypoplastic alae nasi, high-arched or cleft palate, abnormal vestibular function, and hypoplastic ear cartilage. SNHL is either unilateral (15% type I and 5% type II) or more commonly bilateral (20% type I and 55% type II). The loss is usually in the low and mid frequencies and normal hearing for 6,000 to 8,000 Hz. Abnormal vestibular functions are noted in type II but not in type I.

Temporal bone studies were described as absence of the organ of Corti with thickening of the basal membrane and degeneration of the spiral ganglion.

The mode of inheritance is AD with variable penetrance. Of all congenitally deaf children, 3% have Waardenburg syndrome. Its incidence is estimated to be 1 in 20,000 to 1 in 40,000 of the population.

Waardenburg syndrome type I (WSI) and WSIII have been mapped to a distal portion of 2q3 and found associated with PAX3 mutations.

They are considered to be allelic. WSIIis heterogeneous, with about 20% of cases caused by mutations in the human microphthalmia (microphthalmia associated transcription factor, or MITF) gene. Individuals with auditory, pigmentary, or neural crest syndromes that do not fit stringent definitions of Waardenburg syndrome are unlikely to have mutations in either PAX3 or MITF genes (1,2,30).

Figure 107.14 **A,B:** Waardenburg syndrome patients.

FETAL ALCOHOL SYNDROME

Of children born to women who suffer from alcoholism, 30% to 40% suffer from the syndrome. It is characterized by prenatal and postnatal growth deficiency, microcephaly, and an average IQ of 63. Irritability and hyperactivity are common. Seizure disorders have been identified in 10% to 20% of patients. Neural tube defects may be present. Other than the otolaryngologic anomalies, they may have hypoplasia of the optic nerve, increased tortuosity of the retinal vessels, severe microphthalmia, and colobomas. Cardiac, renal, and skeletal anomalies may be present. Malignant neoplasms of embryonal origin have been reported.

Facial dysmorphic features include a narrow forehead, short palpebral fissures, epicanthus, ptosis of the eyelids, midface hypoplasia, a short nose, a smooth philtrum, thin upper lip, and a hypoplastic mandible (Fig. 107.15A–D). A cleft palate or cleft lip may be present. Both conductive and SNHL are frequent.

Alcohol and its major metabolite, acetaldehyde, may be teratogenic. The alcohol-related developmental abnormalities can be the result of restriction of cell growth during critical periods. The amount of alcohol intake to cause the fetal alcohol syndrome is not clearly established (1,31).

Manifestations of Other Syndromes and Conditions

In this section, a few less known syndromes are briefly discussed with emphasis on their systemic and otolaryngologic manifestations.

Aarskog syndrome: The majority of patients have hypertelorism with a broad nasal bridge and forehead, with anteverted nostrils and low-set ears with thick pinnae. The eyes have large corneas, blue scleras, a variety of refractive errors, antimongoloid slants, and latent nystagmus may occur.

The syndrome is characterized by short stature and normal intelligence (90%). The hands and feet are broad. A peculiar feature is the shawl scrotum (a scrotal fold extends

Figure 107.15 **A–D:** Four patients with fetal alcohol syndrome.

dorsally to surround the penile shaft). Cryptorchidism and inguinal herniae are common (1,2,12).

Achondroplasia: This is the most common chondrodysplasia with a frequency of 1:26,000 live births. The skull is large with frontal bossing and small foramen magnum. Partial occipitalization of the atlas and early closure of the sphenooccipital suture occur in most cases. Hypoplasia of the midface with low nasal bridge and recurrent otitis media are also common. Hearing loss may be conductive or sensorineural. Acoustic neuroma and progressive otosclerosis have been described. The limb bones are short and the metacarpals and phalanges are disproportionally large. A small thoracic cage, small horizontally oriented sacrum, and kyphoscoliosis are characteristic manifestations (2,10,12).

Alport syndrome (hereditary nephropathy and deafness): The patients experience a slowly progressive, symmetrical, mild to moderately severe mid- and high-frequency SNHL. The hearing loss occurs as early as age 10. It is important to screen family members as 30% to 50% of relatives may show hearing loss. However, there may be no correlation between hearing loss and kidney function. The basal turn of the organ of Corti shows degeneration of the hair cells and the stria vascularis. Histologic sections show cyst-like vesicle formation under each utricular macule. The syndrome comprises a group of hereditary diseases characterized by progressive defect of capillaries within the glomerular basement membrane of the kidneys (glomerulonephritis). Alport syndrome is classified into six types:

- Type I: AD inheritance. Juvenile onset of end-stage renal disease (ESRD) with SNHL.
- Type II: X-linked dominant inheritance. Juvenile onset of ESRD and SNHL.
- Type III: X-linked dominant inheritance. Adult onset of ESRD and SNHL.
- Type IV: X-linked dominant inheritance. Adult onset of ESRD and normal hearing.
- Type VA: AD inheritance with nephritis, SNHL, macrothrombocytopathy and leucocyte inclusions, also known as Fechtner syndrome.
- Type VB: AD inheritance with nephritis, SNHL, and macrothrombocytopathy, also known as Epstein syndrome.
- Type VI: AD inheritance with juvenile nephritis and SNHL (1,2,12).

Antley-Bixler syndrome: The syndrome is characterized by craniosynostosis, hypoplasia of the midface, proptosis, dysplastic ears, and radiohumeral synostosis with femoral bowing or fractures. The skull is brachycephalic with frontal and biparietal bossing. The anterior fontanel is large. The nose is large and pear-shaped with low nasal bridge. Severe hypoplasia of the midface and choanal atresia or stenosis occur in 80% of the cases. The ears are low set and protruding. Stenosis of the EAC with preauricular tags is occasionally seen. Respiratory depression is the main cause of death in infancy.

Beals syndrome: This is characterized by congenital joint contractures of the knees, elbows, fingers, and ankles. The joint contractures improve spontaneously with time. Most patients are taller than average and exhibit kyphoscoliosis. Intelligence is normal. Otolaryngologic (OTL) manifestations include crumpled pinnae with ill-defined conchae, flattened antihelix, prominent crura, micrognathia, and high arched palate with relatively short neck (1,2).

Beckwith-Wiedemann syndrome: Macroglossia is evident from birth. Prognathism, infraorbital hypoplasia, and capillary nevus flammeus of the face become more obvious in the first year of life. Unusual creases of the ear lobule with indentation of the posterior rim of the helix and concha are seen. Cleft palate or submucous cleft and preauricular pits and conductive hearing loss have been reported. Macrostomia is a constant feature. Visceromegaly involving the kidneys, spleen, and liver is present in the majority of cases. Advanced bone age and widened metaphyses and cortical thickening of the long bones are important features. Intelligence is normal in most patients. Mild hydrocephaly and subdural hematomas are reported. Cardiovascular anomalies include atrial septal defect (ASD), patent ductus arteriosus (PDA), ventricular septal defect (VSD) and Fallot tetralogy. There is increased possibility of developing neoplasms especially embryonal tumors such as Wilm tumor, adrenocortical carcinoma, and hepatoblastoma (2,27).

Binder syndrome: The nose is flat and hypoplastic with absent nasofrontal angle. The nasolabial angle is acute and the nasal septum is atrophied. The sense of smell is preserved. Radiologically, the anterior nasal spine is absent with retrognathia of the maxilla and increased gonial angle. Class III malocclusion may occur. The frontal sinuses are poorly pneumatized and labiomaxillary clefts are occasionally seen. Various anomalies of the first two cervical vertebrae are described. Association of megaesophagus, dysautonomia, and Binder syndrome lead some authors to classify it as a neurocristopathy. Ocular findings include juvenile glaucoma. Cardiac anomalies, diaphragmatic herniae, and genital anomalies are uncommon (1,12).

Coffin-Lowry syndrome: The majority of patients have mental retardation. The syndrome is characterized by square forehead with prominent eyebrows, hypertelorism, and downward-slanting palpebral fissures are characteristic. The nose is short and bulbous with thick septum and flattened alae. Mild facial hypoplasia with thick lips and elongated philtrum. The tongue has a midline furrow and the ears are prominent. Occasionally, SNHL and severe speech retardation are observed. Mild to moderate growth deficiency occurs after birth. Distal muscle atrophy and hypotonia are not uncommon. Finger joints are hyperextensible. Microcephaly and thick calvaria, dilated lateral ventricles and inguinal herniae are occasional findings (1,2,27).

Cohen syndrome: Most individuals are short, obese, and hypotonic with mental retardation. Delayed puberty and downslanting palpebral fissures, and decreased visual acuity are characteristics. Optic atrophy with mottled retina has been described. Open mouth and a short philtrum with exposed upper gingival and prominent upper central incisors characterize the syndrome. Maxillary hypoplasia and micrognathia with high nasal bridge and high narrow palate are also noted. Hyperextensible joints are present in half of the patients. Heart defects may occasionally be observed and rare anomalies include microphthalmia and mild cutaneous syndactyly (2,12).

Cri-du-chat syndrome: Affected individuals exhibit microcephaly, hypotonia, and severe mental retardation. Cardiovascular defects are common, the most frequent being PDA. Diastasis recti, inguinal herniae, talipes, and dislocated hips may occur. The characteristic mewy (cat cry) is present only during infancy and disappears with age in 98% of cases. The origin of the cry is thought to be central rather than due to laryngeal anomaly. Malocclusion and high arched palate occur in most cases. The ears are posteriorly angulated with preauricular tags. The neck is short and the hair is gray in adulthood (1,2,12).

DiGeorge sequence: The sequence may present with cardiovascular and craniofacial features that may be associated with anomalies of the third and fourth pharyngeal pouches. Hypoplasia or aplasia of the thymus and the parathyroid glands result in defective cell-mediated immunity and frequent infections early in life. Patients who survive with milder manifestations are usually moderately to severely retarded. Cardiovascular and thoracic (CVT) anomalies include conotruncal defects. The incidence is 1 in 20,000 births. Craniofacial anomalies include hypertelorism, epicanthal folds, downward-slanting palpebral fissures, anomalies of the lip and palate with choanal atresia, low set ears and posteriorly angulated pinnae with middle ear defects, esophageal atresia, and speech defects are also described (1,2,27).

EEC syndrome (Ectrodactyly-ectodermal dysplasia-clefting syndrome). The majority of patients show absent lacrimal puncti and diminished tearing with dacryocystitis and blepharophimosis leading to photophobia, corneal ulcers, keratoconjunctivitis, and loss of vision. Ectrodactyly usually involves all the extremities. OTL manifestations include cleft lip/palate in the majority of patients. The maxilla is hypoplastic. Other anomalies include missing teeth, dysplastic enamel, and dental caries. Furrowed tongue, xerostomia, and atresia of Stensen ducts are reported. Thirty percent of patients have conductive hearing loss. Dysphonia and malformed auricles with absent stapes are occasionally seen (2,12,27).

Fetal rubella syndrome: The syndrome results from intrauterine rubella virus infection. Effects depend on the time of pregnancy when exposure occurs and may range from no effect to deafness only to the full spectrum of the syndrome. Fetal death may occur or the infant may be born with low birth weight, hepatosplenomegaly, large anterior fontanel, cataract, glaucoma, corneal opacity, and chorioretinitis with microphthalmia. Endocrine anomalies include insulin-dependent diabetes, parathyroid glands problem, and hypopituitarism. Other findings include renal disease, hypospadias, cryptorchidism, and CNS anomalies. Histologically, the inner ear demonstrates partial collapse of the saccule and atrophy of the otolithic membrane. The organ of Corti consists of a thin layer of flattened cells; the stria vascularis is composed of a small layer of compact cells associated with scattered cystic structures (1,2,12,27).

Fragile X syndrome: The presence of a fragile site on the long arm of the 10th chromosome in affected males and some female carriers in one family was described by Lubbs in 1969. The syndrome represents 50% of X-linked mental retardation. The incidence is 1 in 1,250 males. There is increased head circumference and a prominent forehead with broad based nose and prognathism. The ears are large with everted pinnae and absent lobules. Speech is delayed and repetitive phrases are often expressed. The palate is high arched and occasionally cleft with cross-bite or open bite. Motor development is retarded. Patients exhibit hyperactivity, clumsiness, hypotonia, autistic or aggressive behavior, and seizures. Joint laxity in the fingers, knees, and ankles as well as flat feet is described. Mitral valve prolapse with mild aortic dilatation may be associated with this condition (2,12).

Fraser syndrome: Mental retardation occurs in 80% of these patients. Cryptophthalmos is present in the majority of cases and is mostly bilateral. Upper lid coloboma with microphthalmia, symblepharon, and epibulbar dermoid may be present. Anomalies of the ear are described in the majority of patients; they include microtia, low set ears, absent pinnae, and atresia of the EAC. Ossicular anomalies may occur. No inner ear abnormalities are described. Anomalies of the nose may include beaked nose, notched or pinpoint nostrils with choanal atresia, and alar colobomas. Laryngeal atresia or stenosis, fusion of the vocal folds and laryngeal webs are documented. Abnormalities of the genitals occur in 50% to 80% of cases. They include cryptorchidism, hypoplastic penis, large clitoris/labia majora, rudimentary uterus, and vaginal atresia. Renal agenesis has been reported and gonadoblastoma may be found (2,12,27).

Gardner syndrome: The main findings of this syndrome are polyposis of the colon and rectum with tendency toward malignant degeneration, multiple osteomas of the facial bones with cutaneous epidermoid cysts (50% of cases) and fibrous hyperplasia of the skin and mesentery. Other sites of polyposis include the stomach and small intestine. Carcinoma of the ampulla of Vater has been described. Desmoid tumors occur in a high percentage of patients. Osteoma of calvaria, paranasal sinuses, and jaws is commonly seen. The rest of the skeletal system (e.g., radius, ulna, metacarpals) may also be involved. Supernumerary

teeth have also been described. Histologically, a high number of cysts resemble pilomatrixomas (2,12).

Gorlin syndrome: The syndrome is characterized by marfanoid habitus and skeletal anomalies with odontogenic dyskeratotic cysts, intracranial calcifications and predisposition toward basal cell carcinoma of the skin, medulloblastoma, ovarian fibromas, and a variety of other tumors. Calcification of the falx cerebri and cerebelli with lumbarization of the sacrum, vertebral anomalies, spina bifida occulta and pectus excavatum or carinatum may occur in 30% of the patients. Other findings include meningiomas, mesenteric cysts, iris and optic colobomas, cataract and glaucoma with nystagmus, strabismus, and hypogonadism. The nose is broad with mild hypertelorism and mild prognathism, odontogenic keratocysts of the jaws and multiple basal cell nevi that are prone to carcinomatous changes occur over the neck and trunk as well as the face and upper limbs in over 50% of cases. The nevi increase significantly in number around puberty (1,2,12).

Klippel-Feil anomaly: The only constant finding of the syndrome is fusion of the cervical vertebrae due to failure of segmentation of the somites *in utero*. Clinical types are:

- Type I: Extensive fusion of the cervical and upper thoracic vertebrae. It is more common in females.
- Type II: Fusion occurs between two intervertebral spaces. It is inherited as AD and atlanto-axial fusion is often described.
- Type III: Involves fusion of cervical and lower dorsal or lumbar vertebrae.
- Type IV: Encompasses different fusions of the cervical, upper and lower thoracic and lumbar segments. Most cases are sporadic.

Most patients have hearing loss that could be sensorineural or mixed. Inner ear anomalies, vestibular involvement, bifid tongue, cleft palate, velopharyngeal insufficiency, and laryngeal anomalies have also been reported. Other manifestations include convergent squint, nystagmus, and atrophy of the choroid plexus. Scoliosis with or without kyphosis occurs in most patients (1,2,12,27).

Larsen syndrome: It is characterized by flat facies, multiple congenital dislocations, clubfoot deformities, and short finger nails. The nose is flat with hypertelorism and depressed nasal bridge. The forehead is prominent and the palate is highly arched and often cleft. Micrognathia is usually seen. Anomalies of the upper airway include laryngomalacia or laryngotracheal stenosis. Hearing loss can be sensorineural or mixed. Temporal bone findings include dislocation of the incudomalleal joint, abnormal footplate, poorly developed mastoid system, and mesenchymal remnants in the attic and mesotympanum. Bilateral joint dislocation involving the knee, hips, and elbows occurs in the majority of patients. Pseudoclubbing of the fingers, which are cylindrical and have extra creases, occurs in 75% of cases. The eyes are wide and the cervical vertebrae may show kyphosis that could lead to quadriplegia or death. Congenital heart disease, aortic dilatation, and valvular anomalies are also seen (2,12).

LEOPARD syndrome: The acronym comes from *L*entigines, *E*lectrocardiographic abnormalities, *O*cular hypertelorism, *P*ulmonary stenosis, *A*bnormal genitalia, *R*etardation of growth, and *D*eafness (sensorineural). The onset of deafness occurs early in life. The face is triangular with hypertelorism, mild prognathism, low set ears, and mild pterygium colli. Anosmia or hyposmia may occur. Lentigines differ from freckles in being darker in color and having more melanocytes per unit of skin area and are not related to sun exposure. ECG anomalies occur in 50% of subjects and are described as prolonged PR interval, QRS and P wave abnormalities. Compete bundle branch block has also been reported. Pulmonary stenosis is the most common cardiac anomaly. Hypospadias and cryptorchidism are frequently present. Mild mental retardation occurs in 25% of cases (1,2,12).

Marfan syndrome: The syndrome is inherited as an AD trait. The palate is narrow and highly arched, and cleft palate may occur. The teeth are crowded and malocclusion is frequent. Frontal bossing and supraorbital ridges are also noted. The paranasal sinuses are enlarged. Hearing loss may occur and is usually due to recurrent otitis. Temporal bone changes include narrowing of the vestibular aqueduct, bulging round window, dilatation of the endolymphatic duct, and utriculo-ampullary space. Ocular findings include ectopia lentis (50% to 80%), myopia, flat cornea, glaucoma, and retinal detachment may occur. However, 80% of patients have good vision. The ascending aorta is progressively dilated due to cystic necrosis of the media. Mitral prolapse is often seen and musculoskeletal anomalies include arachnodactyly, pectus excavatum or carinatum, and scoliosis. Joints may be hypermobile or congenitally contracted. Pulmonary capacity is reduced and patients may develop pneumothorax. Occasional features include inguinal herniae and neuropsychological problems (1,12).

Miller syndrome: The manifestations of this syndrome include first branchial arch anomalies combined with defects of the extremities, variable degree of mandibulofacial dysostosis with lower lid colobomas, vertebral and rib defects, accessory nipples, and postaxial limb defects.

The malar bones are hypoplastic, the palpebral fissures are downslanted. Colobomas of the lower lids, micrognathia, and cleft palate do occur. The pinnae are hypoplastic and cup-shaped.

Möbius syndrome: Along with cranial nerve palsies, defect of the limbs (adactyly and or syndactyly) as well as hypoplasia or aplasia of the pectoral musculature may be seen. Poland anomaly is seen in 15% of patients. Mild mental retardation has been reported. CVT and urogenital anomalies are rare. Cranial nerve palsies of VI and VII give rise to a masked face if the palsy is bilateral. The most common ocular finding is abducens (VI CN)

paralysis. The mouth is small with drooping angles. The other cranial nerves may be affected as well, XII, IX, V, and III resulting in lingual hypoplasia, dysfunction of the palate, and ocular ophthalmoplegia with conjunctivitis or keratitis. The nose is broad and the mandible is hypoplastic and the ears lack cartilage. Hearing loss is infrequent (2,12).

Multiple mucosal melanoma syndrome (Multiple endocrine neoplasia type IIB or MEM-II): The general manifestations include failure to thrive and marfanoid habitus in the majority of patients with excessive wasting and weakness. Gastrointestinal anomalies such as megacolon with defects of autonomic innervation are also observed. Diverticula and intestinal ganglioneuromatosis have been reported. Pheochromocytoma is documented in half of the patients. Pedunculated neuromas of the palpebral conjunctiva, parathyroid hyperplasia, carcinoid tumors of the rectum, and developmental delay do occur. The multiple neuromas of the tongue and lips are associated with medullary carcinoma of the thyroid, and diagnosis usually occurs after age 12. The syndrome is of AD inheritance; however, half of the cases represent new mutations (1,2,12).

Nager acrofacial dysostosis syndrome (Mandibulofacial dysostosis limb anomalies or preaxial acrofacial dysostosis): Ocular manifestations include lower lid colobomas and a reduced number of cilia. Hypoplastic thumbs are characteristic. Deformities of the toes and radioulnar synostosis are seen in 30% of patients. Other limb deformities include shortened humerus, dislocated hips and rib anomalies. OTL anomalies include bilateral mandibular and malar hypoplasia, downward-slanting palpebral fissures, and absence of the soft palate and high arched palate. EAC anomalies and middle ear deformities are common. The external ears are posteriorly angulated in most patients and preauricular tags may occur. Absent middle ear ossicles or absence of the tympanic membrane was also described. Abnormal larynx and speech defects are known. Hearing loss is usually conductive and air-bone gap up to 50 or 60 dB is not uncommon (2,12).

Noonan syndrome (Ulrich-Noonan syndrome): In this syndrome, birth weight is usually within normal limits or may be increased due to subcutaneous tissue swelling. Prepubertal growth is slow and the pubertal spurt is reduced or absent leading to short stature. Congenital heart defects occur in 60% of patients. Congestive heart failure and pulmonary edema are not rare complications. Pectus deformities as well as cubitus valgus and vertebral anomalies are common. The iris may be blue or blue–green. von Willebrand disease, platelet dysfunction, and factor XI deficiency occur in 25% of the cases. Hypoplastic lymphatic vessels with lymphangiectasia and cystic hygromas occur in a significant number of cases. Hypertelorism, downward-slanting palpebral fissures, deep and elongated philtrum with excess nuchal skin and a low nuchal hairline are common. In infancy, the head is relatively large and the eyelids are thick and hooded. The nose is bulbous and with advanced age the face assumes a triangular shape. Malocclusion occurs in 30% of patients. Sensorineural and conductive hearing loss and language delay may occur (12,27).

Opitz (BBB/G syndrome): Also known as G syndrome or Opitz oculo-genito-laryngeal syndrome. It is characterized by hypertelorism, hypospadias of varying degrees, dysphagia, and anal anomalies. Patients have normal intelligence, mild mental retardation may exist, corpus callosum agenesis was reported. Cryptorchidism and cleft scrotum are seen; however, affected females have normal genitalia. Ectopic and imperforate anus was also documented. Other anomalies include CVT malformations, Meckel diverticulum, duodenal stricture, and agenesis of the gall bladder. The nose is flat with anteverted nostrils and flattened inapparent philtrum. Twenty five percent of patients have cleft lip/palate. Bifid uvula and ankyloglossia may also occur. The ears are posteriorly angulated and micrognathia is present. The cry is usually hoarse and infants have difficulty swallowing. Laryngotracheoesophageal cleft, vocal cord/epiglottis hypoplasia, short trachea, and absent tracheal rings as well as abnormal esophageal mobility have been described. Gastroesophageal reflux was also reported (1,12).

Orofaciodigital syndrome type I (Papillon-Léague-Psaume syndrome): This syndrome comprises oral frenula (70%) and clefts, absent lateral incisors, hypoplastic alae nasi, bifid hallux, digital asymmetry, and mental deficiency (60%). General manifestations include precocious puberty, cerebral atrophy, hydrocephalus, agenesis of the corpus callosum, and hamartoma of the hypothalamus. Webbing occurs between the alveolar ridge and buccal mucous membrane making retraction of the upper lip difficult. The tongue may be bilobed or trilobed and may display hamartomas. Absent lateral incisors and other dental anomalies usually coexist. The mandible is hypoplastic. Choanal atresia is occasionally seen and alopecia with dry scalp has been reported (12).

Orofaciodigital syndrome type II or Mohr syndrome: Characteristics include cleft or lobulated tongue, absent central incisors, polydactyly, partial duplication of the hallux, and conductive hearing loss.

Osteogenesis imperfecta: This is a group of disorders characterized by bone fragility. At least four types of OI exist. Type III is the only recessive disorder of the group. The incidence of all types is 0.5 per 10,000 births. General manifestations include blue sclera that is the hallmark of OI. It is due to an increase in the noncollagenous matrix and molecular disorganization. In type III the blue color fades away after the first year of life. Patients with type IV OI usually have normal sclera. Other ocular anomalies seen in type I are embryotoxon (circular anomalies in the periphery of the cornea), keratoconus, and megalocornea. Long bones display bowing and angulation due to the sparse trabeculae and thin cortex. Type I patients have kyphosis and/or scoliosis in 20% of cases. Macrocephaly and wormian bones are also reported.

Higher incidence of fractures occurs between age 5 and 20. Fifty percent of type III patients demonstrate fractures at birth. OTL manifestations include conductive deafness. By the seventh decade, most patients are deaf, hearing loss may be sensorineural or mixed. The stapes is the most affected ossicle. The footplate is thickened and the crura demonstrate abnormal ossification pattern with thinning or fractures. The temporal bone also exhibits deficient ossification in the facial canal and cochlea. The IAC is grossly widened. Histologically, the stria vascularis may show calcified deposits and the utricle displays abnormal structures. Deafness is more prominent in type I. Type IV patients experience hearing loss 30% of the time. Deafness has not been well documented in types II and III. Dental anomalies include opalescent teeth due to hypoplastic dentin and pulp. Dental caries and malocclusion occur (1,2,12).

Otopalatodigital syndrome type I (Taybi syndrome): This syndrome is characterized by cleft palate, moderate conductive deafness, short stature, short terminal phalanges, and characteristic pugilistic facies (prominent supraorbital ridges, hypertelorism, and broad nasal root). The hearing loss varies between 30 and 90 dB. A variety of ossicular anomalies have been described such as thickened incus, unstable incudostapedial joint, short anterior crus, and wide head of the stapes. Retarded speech occurs due to the hearing loss. The paranasal sinuses and mastoids are poorly pneumatized and the mandibular angle is more obtuse than normal (2,12,27).

Otopalatodigital syndrome type II: The syndrome is characterized by cleft palate, broad forehead, unusual facies, low set ears, short stature, and multiple skeletal anomalies. Death may occur during early life due to feeding and respiratory difficulties. The forehead is prominent with large anterior fontanel, a flat nasal bridge, and cleft palate. Hearing loss is conductive; ossicular deformities include malformed ankylosed stapes and abnormal incus. The mandible is hypoplastic and the facial bones are small and the skull base is thickened (2,12,27).

Smith-Lemli-Opitz syndrome: It is characterized by growth and mental retardation, microcephaly, cleft palate, facial and genital anomalies associated with syndactyly of the second and third toes with postaxial polydactyly of the hands. Failure to thrive occurs in 90% of patients with poor sucking and gastroesophageal reflux. Hypotonia during the newborn period with resultant bronchopneumonia is a frequent feature. Seventy percent of male patients have abnormal external genitalia including hypospadias, cryptorchidism, and microphallus. Various cardiac defects have been reported such as PDA, Fallot tetralogy, and aberrant subclavian artery. Renal defects and incomplete lobation of the lungs have also been described (1,2,12).

Stickler syndrome or hereditary arthroophthalmopathy: Ocular anomalies occur in the majority of patients and include high myopia presenting before age 10, retinal detachment, and cataract. Other eye manifestations include vitreous degeneration, astigmatism, strabismus, and glaucoma. It is important to schedule all patients diagnosed with Robin sequence for ophthalmologic periodic visits since a high percentage of them have Stickler syndrome and may have eye complications. Midfacial hypoplasia with short maxilla and depressed nasal bridge and elongated philtrum are characteristics. Hearing loss (progressive sensorineural or conductive) has been reported in 10% to 80% of patients (2,12).

Sturge-Weber syndrome: The syndrome is characterized by port-wine facial angiomas taking the course of the trigeminal nerve. This is accompanied by intracranial calcifications and seizures in over 90% of cases. Mental deficiency occurs in 30% of patients. Venous angiomas of the leptomeninges are quite characteristic and occur in the temporal, occipital, or parietal regions. With age, the intracranial calcifications mature and detection of vascular angiomas becomes difficult radiologically. Ocular findings include angiomas of the choroid, congenital glaucoma, and hemianopsia. Capillary angiomas of a pink to purplish-red color are seen in almost all the patients. Angiomatosis occurs also on the buccal mucosa or lips and hypertrophy of the tongue may develop. The gingiva may show enlargement and the teeth may display irregular positioning, premature eruptions, and malocclusion. Blue nevus around the trigeminal territory (Ota's nevus) and blue nevus around the shoulder girdle (Ito's nevus) may also be observed (1,12).

Turner syndrome: In this syndrome, growth is stunted and the birth weight is lower than normal. Patients tend to be obese. Cubitus valgus occurs in 70% of patients. Medial exostosis of the knees, short metatarsals, and metacarpals occur (50%). A coarse trabecular pattern is observed on x-ray of the long bones and osteoporosis is observed in older patients. The chest is usually broad with widely spaced nipples. Coarctation of the aorta, hypertension, VSD, and other CVT anomalies occur in 25% of cases. Cochlear anomalies include epicanthal folds, ptosis, and myopia. Ovarian dysgenesis with absent germinal elements is the characteristic of the syndrome. Renal anomalies such as horse-shoe kidney, duplicated renal pelvis, duplicated ureter or unilateral renal aplasia may exist. Anomalies of the ear are common in 80% of patients. They include prominent auricles, abnormal EAC, underdeveloped mastoids, and abnormal stapes. Otitis media is frequent (80%) and conductive or SNHL is documented. The neck is short and webbed with excessive skin in 80% of cases; cystic hygroma has also been reported. Micrognathia with high-arched palate, abnormal dentition, and premature eruptions are frequent occurrences (2,12,27).

van der Woude syndrome: Congenital lip pits are described in this syndrome. They are usually paramedian and bilateral. Occasionally they are asymmetric. They vary in depth from a few millimeters to a few centimeters. They usually occur on the vermillion border of the lower lip.

Hypodontia and missing second premolars and/or bicuspids may occur. The association of cleft lip/palate with lip pits is estimated to be 65%. Submucous cleft is not rare. Adhesions between the maxilla and mandible have been described (2,12).

Whistling face syndrome: Also known as Freeman-Sheldon syndrome. The facies are immobile with microstomia and hypertelorism. An H- or V-shaped crease is usually seen extending from the lower lip to the chin in 30% of cases. The eyes are sunken and strabismus or epicanthus may be seen. The palate is high-arched. The tongue and mandible are hypoplastic. The nose and nostrils are small. Speech is usually nasal. The philtrum is elongated and the cheeks are bulging. Radiologically, the anterior cranial fossa is steep. Conductive and SNHL have been described (1,12).

Williams syndrome: Williams syndrome is a neurodevelopmental disorder of genetic origin, characterized by relative proficiency in language in the face of serious impairment in several other domains. Individuals with this syndrome display an unusual sensitivity to noise, known as hyperacusis. Alterations in sensitivity to input mediate atypical pathways for language development, where hyperacusis exerts an important influence together with other nonauditory factors. Other manifestations include mental retardation (IQ 40–80), reduced motor and perceptual functions, moderate growth deficiency and during childhood, most patients are described as friendly. The nasal bridge is depressed with periorbital fullness, prominent lips and anteverted nares are characteristic. The voice is often brassy and hoarse. Abnormal teeth (microdontia, hypoplastic deciduous second molars, and permanent first molars), delayed dental mineralization, and accessory labial frenula were reported. CVT anomalies include supravalvular stenosis as well as hypoplasia of the aorta, coronary artery stenosis, bicuspid aortic valve, and coarctation. Hypercalcemia, nephrocalcinosis, and renal failure are not uncommon. Blue eyes with stellate pattern of the iris, strabismus, fifth finger clinodactyly, and small penis are other anomalies (12,32).

HIGHLIGHTS

- The presence of three unrelated minor anomalies is associated with 20% risk of major structural defects, and most of these infants will, in fact, have a dysmorphic syndrome.
- The spectrum of dysmorphic phenotypes is broad and includes malformations, deformations, disruptions, sequences, associations, and syndromes.
- The major diagnostic criteria of Apert syndrome are craniosynostosis and syndactyly of the hands and feet.
- The components of CHARGE association are as follows: C (*c*oloboma of the eye), H (*h*eart disease), A (*a*tresia of the choanae), R (*r*etarded development and growth), G (*g*enital anomalies), and E (*e*ar anomalies and/or deafness).
- Down syndrome is the most common of the chromosomal abnormality syndromes. The diagnosis of the syndrome can be made in the early newborn period. Four out of ten signs are needed to make a clinical diagnosis. However, a final diagnosis may be made only after having the results of the chromosomal pattern.
- In Goldenhar syndrome or HMS, the mandibular deformity is graded according to the size of the mandible. "Mandibular distraction" is a new method for ramus elongation for type I, type IIA, and some Type IIB mandibles.
- Most patients with Treacher Collins syndrome have normal intelligence. The manifestations of the syndrome include malformed ears, hypoplastic midface, downslanting of the palpebral fissures, coloboma of the eye lids, and micrognathia.
- The incidence of Usher syndrome is estimated to be 3 to 5 per 100,000 in the general population and up to 10% among the profoundly deaf children. Clinical manifestations are deafness and retinitis pigmentosa.
- Of all congenitally deaf children, 3% have Waardenburg syndrome. Its incidence is estimated to be 1 in 20,000 to 1 in 40,000 of the population. Four clinical types of the syndrome are recognized; type I is the most common.
